

Figure 31.45 Lymphoepithelioma-like carcinoma. This is the same case as Fig. 31.44. There are more epithelial cells than might be expected from the H&E preparation. (Broad keratin immunoperoxidase)

cells with evenly dispersed chromatin; they usually lack the intense admixture of lymphocytes seen in lymphoepithelioma-like carcinomas. The dot-like paranuclear keratin staining in cells of a Merkel cell carcinoma is also distinctive. However, a recent example of Merkel cell carcinoma with a dense, lymphoepithelioma-like lymphoid infiltrate has been reported.¹⁹¹⁵ Cutaneous metastasis from a nasopharyngeal carcinoma is also a diagnostic consideration, but negativity for EBV genomic sequences or evidence of cutaneous adnexal differentiation are points in favor of a primary cutaneous lesion. Lymphoepithelioma-like carcinoma must be distinguished from cutaneous lymphadenoma, a variant of trichoblastoma peppered by lymphocytes (see p. 919). It has also been misdiagnosed as lymphocytoma cutis.¹⁹¹⁶ One recent example of lymphoepithelioma-like carcinoma occurred in a patient with mycosis fungoides. T-cell gene rearrangement studies performed on the biopsy showed monoclonality, with a profile similar to that in the patient's peripheral blood.¹⁹¹⁷ Carcinoma with thymus-like differentiation can also mimic this tumor. The presence of Hassall's corpuscles in the carcinoma with thymus-like differentiation allows a distinction to be made.¹⁹¹⁸

MISCELLANEOUS 'TUMORS'

CUTANEOUS HORN

A cutaneous horn is a hard, yellowish-brown keratotic excrescence: to earn the designation of 'horn', its height conventionally must exceed at least one-half its greatest diameter.¹⁹¹⁹ It may be straight or curved and up to several centimeters in length.¹⁹²⁰ Giant cutaneous horns, grossly similar to the horns seen in animals, are exceedingly rare in humans.¹⁹²¹ Cutaneous horns are usually solitary. They have a predilection for the face, the ears, and the dorsum of the hands of older individuals.¹⁹²² A rare site is the penis.^{1923,1924} It is a clinical entity that may be associated with many different pathological lesions. Most commonly, a horn overlies an actinic keratosis, seborrheic keratosis, inverted follicular keratosis,¹⁹²² trichilemmoma, verruca vulgaris, or squamous cell carcinoma.^{1919,1925,1926} Cutaneous horns of the eyelid often overlie a seborrheic keratosis.¹⁹²⁷ Rarely, there may be an underlying keratoacanthoma, epidermal nevus, lichen simplex chronicus, epidermal cyst, angiokeratoma, or basal cell carcinoma.^{1928,1929} The pathology in the base of the horn is more likely to be premalignant or malignant in lesions with a wide base or a low height-to-base ratio and in lesions occurring

Figure 31.46 Cutaneous horn. In this case, the underlying lesion is a hypertrophic and acantholytic actinic keratosis. (H&E)

on the nose, scalp, forearms, and back of the hands.¹⁹²⁶ There is one report of underlying Kaposi's sarcoma¹⁹³⁰ and one of psoriasis.¹⁹³¹

Histopathology

Horns are composed of keratotic material that may be amorphous or lamellated. Any of the lesions mentioned previously may be present in the base (Fig. 31.46). Occasionally, there is underlying epidermal hyperplasia without cellular atypia, and in these circumstances a 'descriptive' diagnosis of cutaneous horn is appropriate.

The pattern of keratinization is usually epidermal, but a special variant of horn with trichilemmal keratinization has been reported.¹⁹³²⁻¹⁹³⁴ Human papillomaviruses have been suggested as being causally related to these trichilemmal horns on the basis of intranuclear inclusions demonstrated on electron microscopy.¹⁹³⁵ The trichilemmal horns must be distinguished from the so-called 'trichilemmoma horn',¹⁹³⁶ which represents the usual type of horn, with epidermal keratinization, overlying a trichilemmoma. The term 'onycholemmal horn' has been used for a trichilemmal horn on the nail groove.¹⁹³⁷ Nail horns showing epidermal keratinization may also occur, particularly on the big toe.¹⁹²⁰ Filiform parakeratotic horns have also been reported.¹⁹³⁸

Dystrophic calcification is a rare secondary phenomenon in keratin horns.¹⁹³⁹

STUCCO KERATOSIS

The stucco keratosis (keratoelastoidosis verrucosa) has received little attention in the literature, despite its reported incidence in the elderly of approximately 5%.¹⁹⁴⁰⁻¹⁹⁴² Lesions are usually multiple and distributed symmetrically on the distal parts of the extremities, particularly the legs.^{1940,1941} Individual lesions are small (1-4 mm), grayish-white keratotic papules. The surface scale may be scratched off with the finger to reveal a nonbleeding, slightly scaly surface. The lesions have some morphological resemblance to the hyperkeratotic variant of seborrheic keratosis and to tar keratoses, and their continued separation as a distinct entity is of doubtful validity. Several HPV types were detected in one case reported comparatively recently.¹⁹⁴³

Figure 31.47 Clavus. A thick parakeratotic plug is set in a cup-shaped depression of the epidermis. (H&E)

Histopathology^{1940,1941,1944}

Stucco keratoses have prominent orthokeratosis and papillomatosis. There is some acanthosis, often associated with fusion of the rete ridges. There is little or no inflammatory infiltrate in the underlying dermis, which may show some solar elastotic changes. There is no increase in basaloid cells in the lesions, and there are no horn cysts.

CLAVUS (CORN)

A clavus (corn) is a localized callosity that develops a small horny plug, pressure on which is usually painful. It results from pressure or friction, usually from footwear, on the skin overlying a bony prominence.

Histopathology

A clavus is composed of a thick parakeratotic plug set in a cup-shaped depression of the epidermis (**Fig. 31.47**). There is usually loss of the granular layer beneath the plug and thinning of the epidermis. A few telangiectatic vessels may be present in the upper dermis.

CALLUS

A callus is a circumscribed area of hyperkeratosis resulting from chronic friction or pressure. Callosities develop most frequently on the soles, overlying the metatarsal heads, but they may also arise on the hands in manual workers. Other sites may be affected in individuals involved in certain occupations and recreational pursuits. A callus has developed secondary to the friction and pressure on the hand produced by prolonged use of a computer mouse. It has been termed a 'mousing callus'.¹⁹⁴⁵ Plantar pressures are significantly higher under callused regions of the foot in older people.¹⁹⁴⁶ Raised pressure may play a role in their development.¹⁹⁴⁶

Histopathology

The stratum corneum is thickened and compact, resulting in a slight cup-shaped depression of the underlying epidermis. The granular layer may be thickened, in contrast to a clavus (corn) in which it is usually lost (discussed previously). There is usually some parakeratosis overlying the dermal papillae, but much less than in a clavus.

Figure 31.48 Onychopapilloma. (A) Section from an area of distal papillomatosis of the nail bed. There is a keratogenous zone resembling that of the nail matrix (arrows). (B) Section from a more proximal zone of the nail bed showing elongated epithelial rete ridges and a thickened fibrovascular stroma. (H&E)

ONYCHOPAPILLOMA

Onychopapilloma is a term proposed by Baran and Perrin to describe distal subungual keratosis accompanied by a longitudinal ridge of the nail bed. It is associated with longitudinal erythronychia, or sometimes splinter hemorrhage, and distal onycholysis in the area of hyperkeratosis.¹⁹⁴⁷ The clinical differential diagnosis of longitudinal erythronychia includes lichen planus, Darier's disease, amyloidosis, glomus tumor, or Bowen's disease.¹⁹⁴⁷ Longitudinal leukonychia has also been reported.¹⁹⁴⁸

Histopathology

Longitudinal biopsies of the nail bed show acanthosis with distal papillomatosis. In the area of distal papillomatosis, there are fusiform cells with eosinophilic cytoplasm forming stratified layers with a V-shaped configuration at the base, resembling the keratogenous zone of the nail matrix (**Fig. 31.48A**).¹⁹⁴⁷ A thick, fibrovascular stroma is noted in the

involved areas (Fig. 31.48B).¹⁹⁴⁸ Transverse sections through the nail plate show thinning above the epithelial ridge of the proximal nail bed and a cavity in the distal nail bed filled with cornified material.¹⁹⁴⁷

ONYCHOMATRIXOMA

Onychomatrixoma (onychomatricoma), a benign entity described comparatively recently, presents as a yellow discoloration of the nail plate, with transverse overcurvature of the affected nail.¹⁹⁴⁹ Approximately 30 cases have been reported, including 2 in children.^{1950–1952} It may rarely present as longitudinal melanonychia or with nail bleeding.^{1953,1954} A giant variant has been reported.¹⁹⁵⁵ This tumor appears to originate from the nail matrix cells.¹⁹⁵⁶ A variant has been reported as an onychoblastoma,¹⁹⁵⁷ but subsequent correspondence has doubted the separate existence of this ‘entity’ from onychomatrixoma.¹⁹⁵⁸

Histopathology

The tumor is composed of epithelial cell strands originating from the nail matrix and penetrating vertically into the dermis. Some of the strands anastomose. In the central parts of the strands, the keratinocytes evolve into parakeratotic cells, orientated along the axis of the strands.^{1949,1959,1960} The keratinocytes express K14.¹⁹⁶¹ The fibrous stroma is sharply delineated from the tumor cells.¹⁹⁶² If the nail plate is not present, the appearances may resemble a fibrokeratoma. They may be distinguished in longitudinal sections by the presence in onychomatrixoma of epithelial-lined invaginations around optical cavities, a stroma organized in two layers, and the absence of a horny corn (Fig. 31.49).¹⁹⁶¹

Ko *et al.* suggested a new nomenclature to characterize the variability in the histological appearance of these tumors.¹⁹⁵² ‘Unguioblastoma’ has been suggested for tumors with a predominant epithelial component and ‘unguioblastic fibroma’ for tumors where a cellular stroma is more prominent. The term ‘atypical unguioblastic fibroma’ was used by these authors to describe a third rare neoplasm, in which the cellular stroma showed nuclear pleomorphism and atypia with an increase of mitotic activity.¹⁹⁵²

Onycholemmal carcinoma is a completely different entity described by Alessi *et al.*¹⁹⁶³ It is a squamous cell carcinoma variant that in place of the usual horn pearls has cystic structures with abrupt transition between squamous cells and homogeneous keratinized material without the formation of keratinohyaline granules.¹⁹⁶³ In a subsequent case report in 2006, the authors infer that the entity may be the same as subungual keratoacanthoma.¹⁹⁶⁴

The expression of follicular sheath keratins in the normal nail was reported by Perrin in 2007. He found a lack of an inner root sheath-like compartment and of a companion layer. He proposed the terms matrical keratinization and onycholemmal keratinization for the keratinization of the matrix and the nail isthmus, respectively.¹⁹⁶⁵

KERATOACANTHOMA

Keratoacanthoma was first described in 1889 by Sir Jonathan Hutchinson as ‘crateriform ulcer of the face’.¹⁹⁶⁶ Several other terms, including ‘molluscum sebaceum’ and ‘self-healing squamous cell carcinoma’, have been applied since that time; the term ‘keratoacanthoma’ is now universally accepted.^{1967,1968} Notwithstanding this comment, there is a growing trend in some countries to regard keratoacanthoma as squamous cell carcinoma or a variant of it.^{1969,1970} Terms such as ‘squamous cell carcinoma’ and ‘squamous cell carcinoma (keratoacanthoma type)’ are frequently used.¹⁹⁷¹ Their use cannot be justified on morphological or biological grounds. ‘Overcall’ can have as serious consequences for the patient as an ‘undercall’.

Figure 31.49 Onychomatricoma. (A) Epithelial invaginations extend into a cellular, fibrotic stroma and appear to border optically clear cavities. (B) The overlying nail plate shows spike-like processes that previously occupied the clear cavities. Note remnants of epithelium with parakeratosis lining these processes. (H&E)

A keratoacanthoma is most often a solitary, pink or flesh-colored dome-shaped nodule with a central keratin plug developing on the sun-exposed skin of elderly persons. It grows rapidly to a size of 1 or 2 cm over a period of 2–10 weeks. This is followed by a stationary period of similar duration. It has a tendency to involute spontaneously; this takes 8–50 weeks.¹⁹⁷² The duration of the lesion is more variable than is generally recognized, and lesions may persist for more than 1 year without involuting. Clinicians frequently discount the possibility of the lesion being a keratoacanthoma in persistent cases. A keratoacanthoma may cause extensive local destruction, particularly if on the nose or eyelids, before regression occurs, and for this reason active treatment is usually advocated. Healed keratoacanthomas may leave a non-ulcerated, crateriform scar, sometimes resembling a ‘moon crater’.¹⁹⁷³ In contrast, nonfollicular keratoacanthomas, specifically subungual and palmar lesions, usually persist, possibly reflecting a different cell of origin, not having the same programmed life span as the cells in keratoacanthomas arising in hair-bearing skin.¹⁹⁶⁹

Keratoacanthomas develop most often in the older age groups, particularly in the sixth and seventh decades, and there is a male preponderance.¹⁹⁷⁴ A keratoacanthoma has been reported on the lower lip of a 14-year-old boy with discoid lupus erythematosus of the lower lip.¹⁹⁷⁵ A keratoacanthoma developed in a 15-year-old boy in a post-traumatic hypertrophic scar.¹⁹⁷⁶ It is estimated that one keratoacanthoma is diagnosed for every four squamous cell carcinomas of the skin, although keratoacanthomas are proportionately more frequent in subtropical areas.¹⁹⁷⁷ Whereas 70% of lesions develop on the face in temperate climates, there is a much greater tendency for lesions to arise on the arms, dorsum of the hands, and the lower extremity in patients in subtropical areas.¹⁹⁷⁸ In a series of 40 consecutive cases studied by the author (in subtropical Brisbane, Australia), 85% were on the extremities.¹⁹⁷⁹ Nearly all lesions develop on hair-bearing areas (follicular keratoacanthomas), although there are some exceptions, to be mentioned later. Rare sites of involvement include the eyelids,¹⁹⁸⁰ conjunctiva,¹⁹⁸¹ lip,^{1982,1983} mouth,¹⁹⁸⁴ glans penis,¹⁹⁸⁵ vulva,^{1986,1987} perianal region, and male nipple.¹⁹⁸⁸

Nearly all keratoacanthomas are solitary lesions, less than 2 cm in diameter, arising on skin exposed to the sun. They may arise on areas not exposed to the sun.¹⁹⁸⁹ However, there are a number of rare clinical variants that are worthy of mention.^{1967,1990,1991}

Giant keratoacanthoma

The term 'giant keratoacanthoma' is applied to a tumor greater than 2 or 3 cm in diameter. Such lesions have a predilection for the nose and the dorsum of the hands.^{1992–1994} It has been reported on the lip¹⁹⁹⁵ and in hypertrophic lichen planus of the leg.¹⁹⁹⁶

Abortive keratoacanthoma

The author has seen more than 50 cases of a variant of keratoacanthoma in which involution commences at an early stage in its evolution. It is a clinically distinct variant that referring clinicians are able to diagnose with a high degree of accuracy, once they are aware of the entity. The vast majority of cases occur on the lower leg. A striking histological feature of this variant has been the presence of a lichenoid infiltrate in every case that always extends well beyond the proliferative component mimicking a lichen planus-like (lichenoid benign) keratosis.

Keratoacanthoma centrifugum marginatum (multinodular keratoacanthoma)

Keratoacanthoma centrifugum marginatum is a rare variant characterized by progressive peripheral growth with coincident central healing.^{1997–2000} Such lesions may be 20 cm or more in diameter. Most cases occur on the leg,^{2001,2002} but the author has seen cases involving the hand²⁰⁰³ and one case involving the buttock and perianal region. Rarely, multiple lesions form.²⁰⁰⁴ The plaque-like variant reported as keratoacanthoma dyskeratoticum et segregans²⁰⁰⁵ is probably related. The multinodular variant has multiple nodular tumors, usually at the expanding periphery of the lesion.²⁰⁰⁶ In two cases, this variant arose in patients with multiple lesions of Ferguson Smith type.^{2007,2008}

Subungual keratoacanthoma

Subungual keratoacanthoma may be solitary or it may be associated with multiple keratoacanthomas of the common type: in the latter case, more than one subungual lesion may be present. Subungual keratoacanthomas grow rapidly, often fail to regress spontaneously,^{2009–2011} and usually cause pressure erosion of the distal phalanx.²⁰¹² Spontaneous regression of a subungual keratoacanthoma has been reported.²⁰¹³ Paradoxically, they are more destructive than squamous

cell carcinomas in this site.²⁰¹⁴ They appear to be identical to the subungual keratotic tumors found in incontinentia pigmenti.²⁰¹⁵ Subungual keratoacanthomas can be grouped with lesions derived from mucous membranes as nonfollicular keratoacanthomas.¹⁹⁶⁹ The case reported in 2006 as onycholemmal carcinoma may have been a subungual keratoacanthoma.¹⁹⁶⁴

Multiple keratoacanthomas

There are several distinct clinical types of multiple keratoacanthomas.^{2016–2025} These include the Ferguson Smith type,²⁰¹⁷ the Grzybowski (eruptive) type,^{2018,2026–2032} a mixed group with overlap or unusual features,²⁰¹⁹ a limited type in which the keratoacanthomas are restricted to one side or area of the body,^{2020,2033,2034} and a secondary type in which the lesions develop at sites of trauma,¹⁹⁹⁰ treatment, or an underlying dermatosis.²⁰³⁵ The author has seen several cases of keratoacanthomas occurring in the setting of prurigo nodularis and excoriations, examples of which were first described by Emery Kocsard and colleagues in 1972 as 'multiple keratoacanthoma-like neurodermatitis nodularis'.²⁰³⁶ Multiple persistent keratoacanthomas have also been reported.²⁰³⁷ Multiple keratoacanthomas may be associated with internal cancer,^{2038–2040} as in Muir-Torre syndrome, in which multiple keratoacanthomas accompany the presence of a primary visceral cancer, particularly of the gastrointestinal tract.^{2041–2043} Multiple keratoacanthomas may also be associated with malignancies of the genitourinary tract, termed keratoacanthoma visceral carcinoma syndrome.^{2044,2045}

The *Ferguson Smith type* (OMIM 132800) is characterized by the development of a succession of lesions, one or a few at a time, on covered as well as exposed areas of the body, and beginning usually in adolescence.^{1990,2022,2046} These heal, leaving an atrophic and sometimes disfiguring scar. It seems that the variant found in Scottish kindreds is a more aggressive form with an autosomal dominant inheritance and histological appearances that may resemble those found in a squamous cell carcinoma.²⁰²³ The term 'multiple self-healing squamous carcinomas' (MSSE) is still applied to this variant.^{2023,2024} The MSSE gene has been mapped to chromosome 9q31.²⁰⁴⁷ Potential candidate genes in this region, the xeroderma pigmentosum (XPA) gene and the *PTCH* gene, have been excluded. Sporadic cases have been described.²⁰⁴⁴

In the *eruptive Grzybowski type*, there are multiple (often several hundred) papules and nodules of varying size, with an onset in the fifth and sixth decades.²⁰²⁵ Lesions may develop on the palms and soles and mucous membranes, as well as in the more usual sites.²⁰⁴⁸ They may exemplify the Koebner phenomenon.²⁰⁴⁸ The lesions may be intensely pruritic.²⁰²⁵ HPV of epidermodysplasia verruciformis type has been isolated from the lesions in patients with this variant of keratoacanthoma.²⁰⁴⁹ HPV was not detected in another case.²⁰⁵⁰ The *Witten and Zak type* of multiple keratoacanthomas is a rare familial syndrome that combines features of the Grzybowski and Ferguson Smith types.²⁰⁵¹

Etiology

Viruses have long been suggested as an etiological agent, but there are only isolated examples of their discovery in keratoacanthomas in immunocompetent individuals,²⁰⁵² although a more recent study found HPV DNA in 4 of 11 cases tested.²⁰⁵³ However, DNA sequences of HPV of both genital and cutaneous types have been detected in 20–55% of keratoacanthomas in immunosuppressed patients.^{2053–2055} A keratoacanthoma has been reported in a patient with epidermodysplasia verruciformis in whom HPV-5 and unknown types of HPV were detected elsewhere on the skin.²⁰⁵⁶ In animals, chemical carcinogens can produce lesions resembling keratoacanthomas; such tumors develop from the hair follicles.²⁰⁵⁷ Exposure to tars, either industrial or therapeutic, will induce lesions in humans.⁵⁹⁸ Exposure to excessive sunlight is the most

frequently incriminated factor in the etiology of keratoacanthomas.²⁰⁵⁸ Other factors include trauma,^{1990,2059} sometimes surgical,²⁰⁶⁰ immunosuppressed states (in which the keratoacanthomas are prone to aggressive growth, early recurrence, and even transformation into squamous cell carcinoma),¹⁴⁹⁸ chronic renal failure²⁰⁶¹ (although subsequent correspondence suggested these lesions may have been an acquired perforating dermatosis),²⁰⁶² and xeroderma pigmentosum.¹⁹⁸² They have infrequently followed bites, vaccinations,²⁰⁶³ the use of imiquimod,²⁰⁶⁴ arterial puncture,²⁰⁶⁵ burns,²⁰⁶⁶ the smoking of 'Goza' and 'Shisha' in the Middle East,¹⁹⁸³ and PUVA therapy.²⁰⁶⁷ Cases have been reported following the use of sorafenib, which targets many different kinases.²⁰⁶⁸ Keratoacanthomas have also developed following the use of infliximab.²⁰⁶⁹ They have been known to develop in linear epidermal nevus,²⁰⁷⁰ in organoid nevus (nevus sebaceus),^{2071,2072} in prurigo nodularis treated with cryotherapy,²⁰⁷³ and in other cryotherapy sites,²⁰⁷⁴ in a tattoo,^{1971,2075–2077} within an *in situ* malignant melanoma,²⁰⁷⁸ at the site of treated psoriatic lesions,²⁰⁷⁹ and in association with several dermatoses,²⁰⁸⁰ particularly hypertrophic lichen planus.^{1996,2081–2083} They have also arisen in lesions of pseudoxanthoma elasticum.²⁰⁸⁴

Surgery is said to be the treatment of choice for solitary lesions or when the number of lesions is small.²⁰⁴⁴ The author has seen many cases treated by shave excision that have regressed completely, even though a few nests reached the deep edge. Curettage with or without cautery can also be used. Facial lesions can be treated with Mohs surgery. It is essential that active treatment is used for facial lesions because untreated lesions may cause considerable destruction of the face, particularly lesions on the columella of the nose. Other treatments include intralesional injections of methotrexate or 5-fluorouracil,^{1995,2085} intralesional IFN- α ,^{1995,2086} topical imiquimod,^{2002,2087} oral retinoids,^{2004,2007} local radiation,²⁰⁰³ and surgical excision of the growing peripheral border. Retinoids may not be effective with the Grzybowski type,²⁰³¹ although remission has been achieved with cyclophosphamide.²⁰⁴⁸

Histopathology

Because there is no single consistent histological feature that characterizes a keratoacanthoma,²⁰⁸⁸ the diagnosis may cause difficulty for the inexperienced pathologist, particularly if only a snippet biopsy is submitted. However, there should be no difficulty in making a correct diagnosis on excision or shave specimens and in fusiform biopsies, which extend across the central diameter of the lesion for its full width or at least well into its center. A constellation of histological features needs to be assessed. That said, the author regularly diagnoses keratoacanthomas, without equivocation, on 2-mm punch biopsies on the basis of the distinctive pattern of keratinization. A notation to the effect that a superimposed squamous cell carcinoma cannot be excluded is appended to the reports on all such punch biopsies in persons older than the age of 80 years.

Keratoacanthomas are exoendophytic lesions with an invaginating mass of keratinizing, well-differentiated squamous epithelium at the sides and bottom of the lesion. There is a central keratin-filled crater that enlarges with the maturation and evolution of the lesion. Another key feature is the lipping (also known as buttressing) of the edges of the lesion that overlap the central crater, giving it a symmetrical appearance (Fig. 31.50). In some lesions, a keratotic plug overlies discrete infundibula, and a central horn-filled crater is not formed. A well-formed crater containing keratin is present in most regressing (involuting) lesions (Fig. 31.51).

The component cells have a distinctive eosinophilic hue to their cytoplasm, and as they mature, toward the center of the islands of squamous epithelium, they can become quite large (Fig. 31.52). The presence of K14 and K16 throughout the tumor suggests differentiation toward the outer root sheath below the opening of the sebaceous duct.²⁰⁸⁹ Epithelial atypia and mitoses are not a usual feature.

Figure 31.50 Keratoacanthoma. A lesion in the proliferative phase. (H&E)

Figure 31.51 Keratoacanthoma. This regressing lesion has a large keratin plug. (H&E)

Figure 31.52 Keratoacanthoma. The keratinocytes are large, particularly toward the center of the tumor cell nests. (H&E)

There is a mixed infiltrate of inflammatory cells in the adjacent dermis, and this is sometimes moderately heavy. Eosinophils and neutrophils may be prominent, and these may extend into the epithelial nests to form small microabscesses. There is no stromal desmoplasia except in late involuting lesions.²⁰⁹⁰ Extension below the level of the sweat glands is unusual;²⁰⁹¹ if it is present, particularly careful assessment of the other histological features is required. Atypical hyperplasia of the sweat duct epithelium may be present in some cases.²⁰⁹²

A poorly recognized variant of keratoacanthoma that lacks an invaginating pattern and lipping (buttressing) is the 'multiple follicular' variant. Kossard illustrates one in his article on infundibulocystic tumors with the caption 'broad-based verrucous infundibulocystic hyperplasia seen with en plaque variants of keratoacanthoma'.¹⁶⁹⁵

Perineural invasion is an incidental and infrequent finding that does not usually affect the prognosis or behavior of the lesion,^{2093,2094} although local recurrence has been reported in two perioral keratoacanthomas with extensive perineural invasion and intravenous growth (Fig. 31.53).²⁰⁹⁵ Of the 40 cases reported from the author's institution, 27 were from the head or neck region. We found no metastasis in the 35 cases for which follow-up information was available. Local recurrence occurred in only 1 case, and this was not considered to be directly attributable to the presence of perineural invasion.¹⁹⁷⁹ The author has seen a further 30 cases since that publication (Fig. 31.54). Many were received as consultation cases and involved the face; they had management implications with serious consequences for the patient.

Intravenous growth has also been recorded in a keratoacanthoma of the scalp.²⁰⁹⁶ No recurrence occurred, although wider excision was carried out. The author has now seen eight such cases that have had no untoward consequences (Fig. 31.55).

In *keratoacanthoma centrifugum marginatum*, there is progressive involution and fibrosis toward the center of the lesion, although the advancing edge will show the typical overhanging lip with nests of squamous epithelium in the underlying dermis (Fig. 31.56). Collections of mast cells were present in one case.²⁰⁹⁷

Subungual keratoacanthomas contain more dyskeratotic cells (Fig. 31.57) and fewer neutrophils and eosinophils than the usual keratoacanthoma, and their orientation is more vertical.^{2009,2012} The dyskeratotic cells may show focal calcification (Fig. 31.58). Some of the smaller lesions in the various syndromes of multiple keratoacanthomas may show a dilated follicle or cup-shaped depression filled with keratin and showing only limited proliferation of squamous epithelium in the base.

Keratoacanthomas developing in the Muir-Torre syndrome may have an accompanying sebaceous proliferation.²⁰⁹⁸ Absence of staining for one of the mismatch repair gene proteins will also be found.²⁰⁴³

Some authorities believe that the *Ferguson Smith type* of lesion should be separated from keratoacanthoma.²⁰²⁴ There is histological support for this view. The Ferguson Smith tumor may have an indefinite edge, some pleomorphism of cells, and the production of only a small amount of keratin. The infiltrate is usually lymphocytic rather than composed of polymorphs.²⁰²⁴

Keratoacanthoma-like pseudoepitheliomatous hyperplasia has been reported overlying a CD30⁺ anaplastic large cell lymphoma.²⁰⁹⁹ It may also develop in lesions of prurigo nodularis.

Regressing keratoacanthomas continue to show a crateriform configuration with prominent hyperkeratosis and stromal fibrosis. Epidermal hyperplasia is variable, and keratinocytes have a bland appearance, lacking the glassy pink cytoplasm of fully developed lesions.²¹⁰⁰

Electron microscopy

The cells in a keratoacanthoma resemble keratinocytes with abundant tonofibrils and numerous desmosomes.²⁰⁸⁸ Intracytoplasmic desmosomes are sometimes observed.²⁰⁸⁸

Figure 31.53 (A) Keratoacanthoma with perineural invasion. (B) There has been no recurrence after 10 years. (C) Another case with perineural involvement. The large size of the nest relative to the nerve is characteristic. (H&E)

Figure 31.54 (A) Keratoacanthoma with perineural invasion. (B) The involved nerve is shown. This case was diagnosed on biopsy without equivocation by the author. Subsequent excision confirmed the diagnosis. No further treatment was carried out. (H&E)

Differential diagnosis

Distinction of keratoacanthoma from squamous cell carcinoma

Histological features that favor a diagnosis of keratoacanthoma over squamous cell carcinoma include the characteristic low-power architecture with a flask-like configuration and central keratin plug, as well as the pattern of cell keratinization with large central cells that have slightly paler eosinophilic cytoplasm.^{2088,2091,2101} Not every

crateriform lesion is a keratoacanthoma: this architecture can occur in squamous cell carcinomas arising over cartilage, such as on the ear and the base of the nose. The infundibulocystic squamous cell carcinoma described by Kossard *et al.* may closely resemble a keratoacanthoma in its early stages.¹⁶⁹⁵ The pattern of keratinization of the cells resembles a squamous cell carcinoma and not a keratoacanthoma.¹⁶⁹⁵ In keratoacanthomas, the crater is usually multiloculated and the lips are perforated.¹⁹⁸⁹ Other features favoring keratoacanthoma include lack of anaplasia, a sharp outline between tumor nests and stroma,²¹⁰²

Figure 31.55 Keratoacanthoma in a vein. (A) There has been no recurrence. (H&E) (B) The elastic tissue stain confirms this is a vein with intimal thickening. (Verhoeff–van Gieson)

Figure 31.58 Subungual keratoacanthoma. There are calcium salts in the dyskeratotic cells. (Von Kossa stain)

and the absence of stromal desmoplasia. The presence of intraepithelial elastic fibers and intracytoplasmic glycogen has also been said to favor the diagnosis of keratoacanthoma.^{2103,2104} Involucrin, a marker for preterminal squamous differentiation, has been demonstrated by immunoperoxidase methods to be present in all but the basal cells of a keratoacanthoma and in a homogeneous pattern, whereas the staining in squamous cell carcinomas was of variable intensity from cell to cell.^{2105,2106} The volume-weighted mean nuclear volume is higher in keratoacanthomas than in squamous cell carcinomas.²¹⁰⁷ Peanut lectin has been demonstrated in the cell membranes of keratinocytes, in a uniform pattern, in keratoacanthomas but not in most squamous cell carcinomas.²¹⁰⁸ The expression of stromelysin-3, collagenase-3, p21, and the oncoprotein C-erbB-2/neu/HER-2 is higher in squamous cell carcinomas than in keratoacanthomas.²¹⁰⁹⁻²¹¹² Most 'classic' keratoacanthomas showed normal membranous immunostaining for E-cadherin and the catenins, but in cases purported to be 'borderline', the expression of these adhesion molecules resembled that seen in poorly differentiated squamous cell carcinomas.²¹¹³ That is, E-cadherin fails, as a sole marker, in distinguishing difficult cases of keratoacanthoma from squamous cell carcinoma.²¹¹⁴ A study using markers for both the initiation phase (the cytolytic receptor P2X₇) and the end-stage (TUNEL) found them both present in keratoacanthoma. However, strong P2X₇ labeling was also present in squamous cell carcinomas, but the location of this label was quite different from that of keratoacanthoma.²¹¹⁵ The labeling extended more deeply in squamous cell carcinoma.²¹¹⁵ Both PCNA and MIB-1 (raised against recombinant Ki-67 antigen) are found in the periphery of the squamous nests in keratoacanthoma, in contrast to a more diffuse staining pattern throughout the nests in squamous cell carcinomas, although some overlap occurs.²¹¹⁶⁻²¹¹⁹ Expression of the p53 oncoprotein and the p16 tumor suppressor protein is found in both entities.^{185,2117,2120-2123} A recent study showed that subungual squamous cell carcinomas had a higher expression of p53 and Ki-67 than subungual keratoacanthomas.²¹²⁴ Analysis of loss of heterozygosity reveals only low loss in keratoacanthomas, contrasting with the high loss in squamous cell carcinomas.²⁰⁴⁷ Positron emission tomography performed for another purpose showed increased glucose uptake by a keratoacanthoma.²¹²⁵ Nuclear factor κ B p50 subunit (p50), a pleiotropic transcription factor, and contactin, a cell adhesion molecule of the immunoglobulin superfamily, have high levels of expression localized to the basal cell layer of keratoacanthomas but scattered expression throughout squamous cell carcinoma lesions; they may prove to be helpful markers in differential diagnosis.²¹²⁶ Using fluorescence *in situ* hybridization analysis and immunohistochemistry, Jacobs *et al.* found that EGFR and MYC gene copy aberrations were more common in squamous cell carcinoma than in keratoacanthoma, and that the incidence of these aberrations paralleled the degree of cytologic atypia in keratoacanthomas.²¹²⁷

Other differential diagnostic considerations

Keratoacanthoma can have a close resemblance to hypertrophic lichen planus. In a study investigating possible means of differentiating the two lesions, Bowen *et al.* found that although p53 and MIB-1 (a marker for Ki-67) are more strongly expressed in keratoacanthoma, there is sufficient overlap with hypertrophic lichen planus to limit the diagnostic value of these stains. However, transepidermal elimination of elastic fibers, as assessed by Verhoeff-van Gieson staining, is commonly found in keratoacanthomas but not typically found in lesions of hypertrophic lichen planus.²¹²⁸

Behavior of keratoacanthomas

The literature contains many examples of lesions that on clinical, and sometimes even pathological, grounds were regarded as keratoacanthomas but that on the basis of their subsequent course were reclassified

as squamous cell carcinomas.^{2091,2129} There are four possible explanations for this occurrence.²¹²⁹ First, the initial diagnosis of keratoacanthoma could have been wrong; this is the usually accepted and most likely explanation.²¹⁰¹ Second, the initial lesion may have combined a keratoacanthoma and a squamous cell carcinoma. Third, a keratoacanthoma may have transformed into a squamous cell carcinoma, either as a result of therapy or at some point in its evolution (see later).^{2130,2131} Fourth, keratoacanthoma may actually be a variant of squamous cell carcinoma, as had been proposed by Ackerman.^{2132,2133} The author believes with strong conviction that the biological potential and histopathology of keratoacanthomas and squamous cell carcinomas are so different that their continued separation is essential if mistreatment of keratoacanthomas with perineural and/or venous invasion is to be avoided.

The author has seen many examples in which part of the lesion was an undoubted keratoacanthoma but in which, usually toward the base or at one edge, there were areas of typical squamous cell carcinoma. Support for the concept of malignant transformation of keratoacanthoma comes from animal experiments in which UV irradiation of hairless mice produced some squamous cell carcinomas that appeared to arise in keratoacanthomas.²¹³⁴ This transformation also occurs in immunocompromised patients and in the very elderly.²¹⁰¹ In 2000, Sánchez Yus and colleagues reported focal squamous cell carcinoma change in at least one-fourth of all cases.¹⁹⁸⁹ This is considerably higher than the author's anecdotal experience of approximately 3%. One explanation might be that keratoacanthoma in subtropical countries is not the same as in temperate lands. However, with the aging of the population, this phenomenon of squamous cell carcinoma arising in a keratoacanthoma is becoming more common. In a series of 3465 cases of keratoacanthoma seen during a 14-month period, Weedon *et al.* found the development of squamous cell carcinoma in 200 cases, for an incidence of 5.7%. The incidence was 3.6% in patients younger than 70 years of age and 13.9% in those 90 years of age or older. Perineural invasion was found in 7 (0.2%) of the 3265 cases of 'pure' keratoacanthoma and in 1 (0.5%) of the 200 cases of squamous cell carcinoma arising in a keratoacanthoma; most examples of perineural invasion were in the head and neck region.²¹³⁵ Incidentally, the contrast between the two components is often striking. There are usually no transitional areas. The risk of squamous cell transformation in keratoacanthomas from patients older than age 85 years is also high.

It should be remembered that keratoacanthomas can recur in up to 8% of cases.²¹³⁶ Recurrence is more likely with lesions on the fingers, hands, lips, and pinnae.²¹³⁰ Lesions on the nose and eyelids can be very destructive.^{1980,2137}

Metastasis

The published photomicrographs accompanying a report of a giant metastasizing keratoacanthoma show a pattern of keratinization more in keeping with a squamous cell carcinoma than a keratoacanthoma.²¹³⁸ Ackerman and colleagues have reported three cases purporting to be keratoacanthomas in which metastasis occurred.²¹³² On this basis, they concluded that keratoacanthoma is a squamous cell carcinoma.²¹³²

Regression

The mechanism responsible for the regression of keratoacanthomas is still poorly understood. There is only limited evidence that regression is immunologically mediated. Activated CD4⁺ T lymphocytes expressing IL-2R are present in the infiltrate.²¹³⁹ Langerhans cells are also increased.²¹⁴⁰ As previously mentioned, lymphocytic regression is a characteristic feature of the abortive variant of keratoacanthoma. Deletion of many of the cells in the usual keratoacanthoma results from their maturation and keratinization, with subsequent extrusion as a keratin plug. Other cells show dyskeratotic changes (filamentous degeneration), and these tonofilament-rich masses are extruded into the stroma, where they become incorporated into the dermal collagen.

Still other cells undergo cell death at an earlier stage by the process of apoptosis. It is worth recalling that many keratoacanthomas appear to arise from hair follicle epithelium: in the normal follicle, the cells have a programmed ability to be deleted by apoptosis, resulting in catagen involution of the follicle. The author is aware that the infundibulum does not participate in catagen, but this does not negate this analogy. The author has seen two cases of keratoacanthoma, one with perineural invasion in which multiple small (infundibular) milia persisted in the scar following involution of the deeper keratoacanthoma. Expression of *BCL-2*, a proto-oncogene that inhibits apoptosis, is lost in regressing keratoacanthomas.²¹⁴¹ It has been found that expression of the cyclin-dependent kinase inhibitor p27 is elevated

significantly in regressing keratoacanthomas when compared with growing lesions.²¹⁴² This protein induces a G₁ block in the cell cycle. Another study found sialyl-Tn, a tumor-associated carbohydrate expressed on the cell surface, more often in keratoacanthomas than in squamous cell carcinomas. It may be linked to the regression of keratoacanthomas.²¹⁴³

Lentigines, nevi, and melanomas

Gregory A. Hosler and James W. Patterson

32

Introduction	838	Deep penetrating nevus	848	Blue nevus-like metastatic melanoma	861
Lesions with basal melanocyte proliferation	838	Balloon cell nevus	849	Malignant blue nevus	861
Lentigo simplex (simple lentigo)	838	Halo nevus	849	Dermal melanocyte hamartoma	862
Multiple lentigines	838	Cockarde nevus	850	Phakomatosis pigmentovascularis	862
Labial, genital, and other melanotic macules	839	Eccrine-centered nevus	850	Cutaneous neurocristic hamartoma	863
Solar (senile) lentigo	839	Recurrent nevus	850	Paranglioma-like dermal melanocytic tumor	863
Lentiginous nevus	840	Sclerosing nevus	851	Atypical nevomelanocytic lesions	863
Speckled lentiginous nevus (nevus spilus)	841	Spitz nevus	851	Dysplastic (atypical, Clark's) nevus	863
PUVA lentigo	841	Atypical Spitz nevus (tumor)	855	Lentiginous dysplastic nevus of the elderly	866
Scar lentigo	841	Halo Spitz nevus	855	Malignant melanocytic lesions	866
Melanocytic nevi	842	Desmoplastic nevus	855	Melanoma	866

INTRODUCTION

The histopathological diagnosis of pigmented skin tumors is an important area of dermatopathology. Note that melanin pigment may also be present in skin tumors other than nevocellular nevi and melanomas. For instance, seborrheic keratoses, basal cell carcinomas, and, rarely, squamous cell carcinomas, schwannomas, and dermatofibrosarcoma protuberans may contain melanin. Furthermore, there is a group of dermatoses characterized by variable patterns of hyperpigmentation covering, at times, significant areas of the body.¹ This chapter is devoted to proliferative disturbances of the melanocyte-nevus cell system. Other disorders of pigmentation are considered in Chapter 10.

LESIONS WITH BASAL MELANOCYTE PROLIFERATION

Lesions with basal melanocyte proliferation are characterized by basal hyperpigmentation and an increase in melanocytes in the basal layer. The melanocytes are usually single and cytologically normal. Small junctional nests are sometimes seen. Epidermal acanthosis and the presence of melanophages in the papillary dermis are additional histological features that are usually seen in entities within this group.

In addition to the lesions discussed here, melanocytic hyperplasia can occur in lichen simplex chronicus, in the skin of the eyelid of elderly patients, and in sun-damaged skin.² The proliferation of melanocytes in skin exposed to the sun is sometimes mildly atypical, and this may pose difficulties when it is present near the edge of an excision specimen.

LENTIGO SIMPLEX (SIMPLE LENTIGO)

The simple lentigo is a brown to black, sharply circumscribed and usually uniformly pigmented macule, measuring a few millimeters in diameter. It may be found anywhere on the body surface.³

The term 'labial melanotic macule' is now used for a clinically similar lesion on the lip that was previously referred to as a lentigo (see later).

Histopathology

There is variable basal hyperpigmentation with an increased number of single melanocytes in the basal layer. There is usually acanthosis, with regular elongation of the rete ridges. The papillary dermis may contain a sparse lymphohistiocytic infiltrate, including scattered melanophages (Fig. 32.1). Some lesions evolve with the formation of nests of melanocytes in the junctional zone,⁴ but it is best to designate these lesions with mixed features of a lentigo and a junctional or compound nevus as lentiginous nevi.

MULTIPLE LENTIGINES

Various syndromes characterized by the presence of numerous lentigines developing in childhood or adolescence have been described.^{1,3} The pigmented macules may be unilateral in distribution,⁵⁻⁸ agminated,⁹ or generalized,¹⁰⁻¹² the latter form sometimes being a marker of an underlying developmental defect (see later).¹³ The terms 'lentiginous mosaicism' and 'partial lentiginosis' have been used for cases with regional or segmental lesions,^{1,14,15} but the older term 'lentiginosis profusa' is still used sometimes for cases of multiple lentigines with or without associated abnormalities. Partial unilateral lentiginosis colocalized with nevus depigmentosus has been reported.^{16,17} Partial (segmental) lentiginosis differs from speckled lentiginous nevus (nevus spilus) by

Figure 32.1 Lentigo simplex. There is mild elongation of pigmented rete ridges. A few scattered lymphocytes and melanophages are present in the papillary dermis. (H&E)

occurring on normal skin, in contrast to the background of macular pigmentation seen in speckled lentiginous nevus.¹⁸⁻²²

Multiple (generalized) lentigines may develop as an eruptive phenomenon in the absence of systemic abnormalities.²³ Rare familial cases of eruptive lentiginosis have been reported.²⁴ Other cases are associated with internal manifestations in several rare syndromes: the LEOPARD syndrome, the NAME and LAMB syndromes, and centrofacial lentiginosis.²⁵ For the Peutz-Jeghers syndrome (see p. 337), there are conflicting views as to whether the lesions are lentiginous (with an increased number of melanocytes) on histological examination.²⁶

The LEOPARD syndrome (OMIM 151100) is inherited as an autosomal dominant trait.²⁷⁻³⁰ It is characterized by lentigines (L), electrocardiographic conduction defects (E), ocular hypertelorism (O), pulmonary stenosis (P), gonadal hypoplasia (A), retarded growth (R), and nerve deafness (D). Hyperplastic skin may be present.³¹ A choristoma was present in one case.³² These features are not all present in every case. Some cases are due to mutations in the *PTPN11* gene; sporadic cases also occur.^{25,33,34} LEOPARD syndrome has been associated with *PTPN11* (a protein tyrosine phosphatase gene), *RAF1*, and *BRAF* germline mutations.³⁵ A malignant melanoma has developed in a woman with LEOPARD syndrome who carried a germline *PTPN11* mutation and a somatic *BRAF* mutation.³⁶

The NAME syndrome is another rare cardiocutaneous syndrome.³⁷ Its features include nevi (N) as well as lentigines, ephelides and blue nevi, atrial myxoma (A), myxoid tumors of the skin (M), and endocrine abnormalities (E). A similar syndrome has been reported as the LAMB syndrome: mucocutaneous lentigines (L), atrial myxoma (A), mucocutaneous myxomas (M), and blue nevi (B).³⁸ The NAME and LAMB syndromes are now referred to collectively as Carney complex (OMIM 160980),^{39,40} although this properly refers to multiple lentigines and blue nevi, melanotic schwannoma, myxomas, and endocrine overactivity.⁴¹ Carney complex is associated with germline mutations in *PRKARIA* (a protein kinase A gene).^{42,43} A variant of Carney complex has been described with mutations in *MYH8* (myosin heavy chain 8).⁴⁴ Lentigines have been reported in association with an atrial myxoma,¹³ blue nevi,⁴¹ strabismus,⁴⁵ flexural pigmentation,⁴⁶ and segmental achromic nevi.^{7,47} Several cases of lentigines have been reported in children with atopic dermatitis treated with topical tacrolimus.⁴⁸

It has been suggested that acral lentigines are a new paraneoplastic syndrome.⁴⁹ The authors reported four cases with this association.⁴⁹ Eruptive melanocytic macules have also been reported as a paraneoplastic phenomenon.⁵⁰

LABIAL, GENITAL, AND OTHER MELANOTIC MACULES

Melanotic macules are flat, well-defined melanocytic lesions with abundant melanin in the basal layer of the epidermis, accompanied by a slight increase in the number of melanocytes.² Included in this category are the labial (oro-labial) melanotic macule, the genital (vulvar and penile) melanotic macule, melanoses of the areola and conjunctiva, and melanotic macules of the nail bed and matrix.

The *labial melanotic macule* is a pigmented lesion of the lip that may occur in up to 3% of the population.⁵¹ Previously, lesions of this type were classified as lentigines. It presents as a tan-brown to brown-black macule, 2–15 mm in diameter, on the vermillion border of the lip, particularly the lower.^{52–54} Multiple lesions may be present.⁵¹ They tend to remain stable and unchanged when followed over a long period. Oral and labial melanotic macules appear to be more common in patients infected with the human immunodeficiency virus.⁵⁵ Labial melanotic macules have occurred following the use of tacrolimus ointment (lentigines have also reportedly been induced by this agent).⁵⁶

'*Genital melanotic macules (genital lentiginoses)*' are similar lesions, up to 2 cm in diameter, that develop uncommonly on the penis and vulva.^{57–59} These are sometimes referred to as 'penile melanosis' and 'melanosis of the vulva', respectively.^{60,61} Pigmented vulvar macules were the presenting feature of Carney's complex (see p. 417) in one case.⁶² A ring-like pattern has been observed on dermoscopy of vulvar lesions.⁶³

Only a few cases of *melanosis of the areola* have been reported. The nipple may also be involved.⁶⁴

Melanotic macules of the nail bed and matrix present as longitudinal, narrow bands of pigmentation (melanonychia striata).⁶⁵ It is usually sharply defined and less than 3 mm in width, in contrast to the pigmentation produced by subungual melanomas.² Nevus and inflammatory diseases can also be associated with longitudinal melanonychia (see p. 845).

The oral melanoacanthoma (mucosal melanotic macule – reactive type, oral melanoacanthosis) is sometimes included in this group of lesions.^{66–69} They may be solitary or multifocal.⁷⁰

Histopathology

In the *labial melanotic macule*, there is prominent hyperpigmentation of the basal layer that is accentuated at the tip of the rete ridges (Fig. 32.2). There is only mild acanthosis, in contrast to the regular elongation of the rete ridges found in the lentigo simplex. Melanocytes are said to be normal in number or slightly increased; in some cases, they have prominent dendritic processes containing melanin pigment, which can be seen between the keratinocytes of the lower epidermis. These melanocytes are HMB-45 negative.⁵⁴ Melanophages are present in the papillary dermis in approximately half of the cases.

Genital lesions are histologically similar, although melanophages are almost invariably present.⁷¹ When genital lentigines are superimposed on lichen sclerosus, there are melanophages in a fibrosed papillary dermis, with some features of a regressed melanoma. Similar atypical lesions are present in genital nevi associated with lichen sclerosus.⁷²

Melanosis of the nipple and areola shows acanthosis and basilar hypermelanosis. Scattered single basilar melanocytes can be observed with microphthalmia transcription factor.⁷³

The lesions reported as *volar melanotic macules* appear to be heterogeneous, with some resembling postinflammatory pigmentation. Dendritic melanocytes and epidermal hypermelanization were present

Figure 32.2 Labial melanotic macule. There is basal pigmentation limited to the tips of the rete pegs. Melanocytes appear normal. This entity is considered here because it was regarded in the past as a variant of lentigo. (H&E)

in a case reported in an elderly female.⁷⁴ They were reported as the volar counterpart of mucosal melanotic macules.⁷⁵

Melanotic macules of the nail bed are characterized by an increase in melanocytes that have dendritic processes containing melanin granules. The melanocytes can be very difficult to see. The periodic acid–Schiff (PAS) stain can be used to heighten the staining of melanin.⁷⁶ The S100 stain highlights the dendritic melanocytes. This entity accounts for only a small number of cases of melanonychia in some races.⁷⁷

The *oral melanoacanthoma* is characterized by dendritic melanocytes of benign morphology at all levels of the acanthotic epithelium, in contrast to their basal location in lentigines and labial melanotic macules.

Dermoscopy of the labial melanotic macule shows linear and curved brown lines in a parallel pattern.⁷⁸ Reflectance confocal microscopy findings include numerous markedly dendritic melanocytes around dermal papillae at the dermal–epidermal junction.⁷⁹ Melanosis of the areola has dermoscopic features of light to dark brown cobblestone pigmentation with reticulation and ring-like structures.⁷³

SOLAR (SENILE) LENTIGO

Solar lentigines are dark brown to black macules, 3–12 mm or more in diameter, that develop on the sun-exposed skin of middle-aged to elderly patients. They are often multiple. They are considered to be a hallmark of aged skin.⁸⁰ The term '**ink-spot**' **lentigo** is sometimes used for a clinical variant characterized by its black color and a markedly irregular outline, resembling a spot of ink on the skin (Fig. 32.3).⁸¹ The '**ink-spot**' lentigo (reticulated melanotic macule of the trunk) has also been regarded as a melanotic macule along with labial and genital melanotic macules.² Solar lentigines may increase slowly in size over many years. The ABCD rule (Asymmetry, irregular Border, Color variegation, Diameter larger than 6 mm), which comprises clinical criteria for the diagnosis of melanomas and their distinction from nevi, is not applicable to all solar lentigines and some early lentigo malignas. Dermoscopy is more reliable.⁸² Solar lentigines may evolve into the reticulate form of seborrheic keratosis, with such lesions developing a slightly verrucose surface.⁸³

Solar lentigines increase with age. They are related to freckling during adolescence and frequent sunburns during adulthood.^{84,85} They appear to be a common precursor lesion of malignant melanoma in patients with xeroderma pigmentosum.⁸⁶

Figure 32.3 'Ink-spot' lentigo. There is heavy pigmentation of the basal layer. There is mild acanthosis. (H&E)

Gene expression profiling of solar lentigo shows upregulation of genes related to inflammation, fatty acid metabolism, and melanocytes and downregulation of cornified envelope-related genes, suggesting that solar lentigo is induced by the mutagenic effect of repeated ultraviolet light exposures in the past, leading to enhancement of melanin production, together with decreased proliferation and differentiation of lesional keratinocytes.⁸⁰ Another study concluded that multiple solar (senile) lentigines on the face are an aging pattern resulting from a life excess of intermittent sun exposure in dark-skinned Caucasians.⁸⁷ Solar lentigines on the upper back are an earlier stage of this phenomenon.⁸⁷ Abnormal pigment retention in keratinocytes appears to be the primary defect in solar lentigo, which may partly explain the therapeutic effect of retinoids.⁸⁸ A case can be made for their removal from this chapter because keratinocytic changes predominate over melanocytic changes.⁸⁸ Heparanase, activated by ultraviolet exposure, induces a loss of heparan sulfate at the dermal–epidermal junction, which may promote the hyperpigmentation that occurs in solar lentigo.⁸⁹ There is also evidence that fibroblasts, activated by ultraviolet exposure, may release melanogenic growth factors that act directly, or indirectly through keratinocytes, to contribute to the hyperpigmentation associated with solar lentigines.⁹⁰

The treatment of solar lentigines has been the subject of a consensus commentary by the Pigmentary Disorders Academy.⁹³ It recommended ablative therapy using cryotherapy as first-line therapy.⁹³ This body also believes that there is evidence that lasers are an effective treatment. An alternative to ablative therapy is topical therapy, and there is evidence to support the use of a fixed double combination such as hydroquinone and tretinoin.⁹³ Tazarotene and other retinoids can also be used. One study found that cryotherapy shows better results than trichloroacetic acid 33% solution in the treatment of solar lentigo.⁹⁴

Histopathology

The solar lentigo is characterized by elongation of the rete ridges, which are usually short and bulb-like (Fig. 32.4). As they extend more deeply into the dermis, finger-like projections form and connect with adjacent rete ridges to form a reticulate pattern resembling that seen in the reticulate type of seborrheic keratosis.^{83,95} Rete ridge hyperplasia is less conspicuous, and may be absent, in lesions from the face.⁹⁶ In addition, there is basal hyperpigmentation, which is sometimes quite heavy. There is an increased number of melanocytes, particularly at

Figure 32.4 Solar lentigo. There is hyperpigmentation of the bulbous rete ridges. Lesions on the face do not have bulbous downgrowths. (H&E)

the bases of the clubbed and budding rete ridges;⁹⁵ sometimes the increase is not appreciated on casual examination. Variable numbers of melanophages are present in the papillary dermis. These melanophages are factor XIIIa⁺ dermal dendrocytes.⁹⁷ When solar lentigines undergo regression, they develop a heavy lichenoid inflammatory cell infiltrate in the papillary dermis. These features are referred to as a lichen planus-like keratosis (see p. 51).

The author has seen a number of cases of lentigo maligna (Hutchinson's melanotic freckle) developing in solar lentigines. The presence of transitional features (unstable solar lentigo) suggests that this is not a 'collision phenomenon'. Others have also documented this transformation.^{86,98}

Electron microscopy

The melanosome complexes are much larger than those found in non-involved skin.⁹⁵

Differential diagnosis

The distinction between solar lentigo and melanoma *in situ* (most often lentigo maligna or lentiginous melanoma *in situ*) can be a difficult one that sometimes requires the use of immunohistochemical staining to better assess the degree of melanocytic proliferation in the context of basilar hypermelanosis. A common method uses melan-A or MART-1 with azure blue counterstaining, the latter staining melanin blue-green to distinguish it from the brown staining of melanocytes associated with the chromogen diaminobenzidine. The study by Hillesheim *et al.* indicates that the nuclear stain microphthalmia transcription factor (MiTF) is as effective as the MART-1/azure blue method in distinguishing between solar lentigo and melanoma *in situ*, and it has the advantage of not requiring the additional counterstain.⁹⁹ Morphometric analysis of sections stained with MiTF can further enhance diagnostic accuracy by enabling quantification of melanocyte density and nuclear diameter.¹⁰⁰

The dermoscopic features of solar lentigines and their distinction from melanoma have been well studied.⁹¹ Pigmented corneocytes are a feature of the 'ink-spot' lentigo on dermoscopy.⁹² Melanoma *in situ*, in the form of lentigo maligna, features asymmetrical pigmented follicular orifices, rhomboidal structures, annular–granular structures, and a gray pseudo-network,¹⁰¹ whereas solar lentigo is characterized by comedo-like openings, diffuse opaque-brown pigmentation, light brown fingerprint-like structures, or milium-like cysts.¹⁰²

LENTIGINOUS NEVUS

The lentiginous nevus is a neglected entity that appears to represent the evolution of a lentigo simplex into a junctional and sometimes a

compound nevus.⁴ It has also been called nevoid lentigo and nevus incipiens.¹⁰³ They are well-circumscribed, sometimes deeply pigmented, often quite small lesions, found most frequently on the trunk of adults between the ages of 20 and 40 years.

Histopathology

At the advancing edge, there is a lentiginous proliferation of melanocytes resembling that seen in a simple lentigo, whereas in the more central areas there is junctional nest formation and sometimes a small number of mature intradermal nevus cell nests as well. Elongation of the rete pegs and some melanophages in the papillary dermis are usually present.

The **hypermelanotic nevus** appears to be a closely related entity characterized by dark brown to black macules or papules, often on the back, and prominent melanin pigmentation histologically.¹⁰⁴ The pigment is present in the stratum corneum, in keratinocytes and nevomelanocytes in the basal layer, and in melanophages in the upper dermis.¹⁰⁴

SPECKLED LENTIGINOUS NEVUS (NEVUS SPILUS)

Speckled lentiginous nevus is the preferred term for a lesion composed of small dark hyperpigmented speckles, superimposed on a tan-brown macular background.^{103,105} Lesions are present at birth or appear in childhood.¹⁰⁶ As such, they have been regarded as a variant of congenital nevus.¹⁰⁷ They may have a zosteriform or regional distribution.¹⁰⁸ Rarely, lesions are widespread.¹⁰⁹ Similar cases have been reported as nevus spilus,¹¹⁰ but this does not accord with the original use of this term. The term 'zosteriform lentiginous nevus' has also been used synonymously, but it is sometimes used for speckled lesions without the background macular pigmentation.^{111,112} These latter lesions are best regarded as variants of partial lentiginosis. However, the occurrence of cases of speckled pigmentation in which only part of the lesion has a background of macular pigmentation suggests that overlap cases between speckled lentiginous nevus (nevus spilus) and partial (segmental) lentiginosis occur.^{113,114} Finally, the term 'spotted grouped pigmented nevus' has been used for a closely related lesion.¹¹⁵ Malignant melanoma has been reported as a very rare complication.^{116–125}

It has been suggested that there are two distinct types of speckled lentiginous nevi characterized by macular versus papular speckles. The *macular* variant is characterized by a tannish-brown background with darker flat speckles in a polka-dot pattern. The *papular* variant shows multiple melanocytic nevi in the form of papules or nodules in an uneven distribution superimposed on a light brown macule.¹²⁶ Whereas the macular variant appears to be associated with phakomatosis pigmentovascularis (see p. 862), the papular variant is typically present in speckled lentiginous nevus syndrome and in phakomatosis pigmentokeratotic.¹²⁶

Speckled lentiginous nevus (nevus spilus) is one of the components of at least two of the subtypes of phakomatosis pigmentovascularis, which combines vascular and pigmentary malformations (see p. 863).¹²⁷ Multiple speckled lentiginous nevi have been reported in a patient with tuberous sclerosis.¹²⁸

Histopathology

Whereas the background pigmented area resembles lentigo simplex, the speckled areas usually show the features of a lentiginous nevus with lentigo-like areas progressing to junctional and even small compound nevi.^{103,129} An associated old neurotized nevus was present in one case,¹³⁰ whereas in another the dermal component resembled a congenital and a blue nevus.¹³¹

If two variants are recognized (discussed previously), the *macular* variant shows a background lentigo, with superimposed dots of 'jentigo', representing a lentigo with focal junctional nesting at the tips

of the papillae. The *papular* component consists of dermal or compound melanocytic nevi.¹²⁶

Atypia of the intraepidermal melanocytes is an uncommon change in speckled lentiginous nevi; it may be a predisposing factor for the development of a malignant melanoma, a rare complication.¹¹⁶ A small number of large, atypical melanocytes are present in the multiple pigmented lesions that have been reported in occasional patients receiving systemic 5-fluorouracil.^{132,133}

PUVA LENTIGO

Freckles,¹³⁴ lentigines,^{135,136} and nevus spilus-like pigmentation¹³⁷ have been reported in patients treated with psoralens and ultraviolet-A radiation (PUVA), particularly in sun-protected sites such as the buttocks.^{138,139} Palmoplantar involvement has also been recorded.¹⁴⁰ Lesions may involve vitiligo-affected skin¹³⁹ or be confined to plaques of mycosis fungoides.¹⁴¹ There is confusion in terminology in the literature concerning PUVA-induced pigmentary changes.¹⁴² Clinically similar lesions have resulted from exposure to UVA radiation, without concomitant psoralen administration, in tanning parlors.^{143,144} Similar lesions have developed following accidental exposure to ionizing radiation.¹⁴⁵

Although lentigines have been reported in patients with psoriasis who have undergone PUVA therapy, they have also been reported in psoriatic plaques not subject to PUVA therapy.¹⁴⁶

Histopathology

Many of the lentigines have relatively large, even cytologically atypical, melanocytes in the basal layer (**Fig. 32.5**).¹⁴⁷ Melanoma *in situ* change and malignant melanoma have also been reported.^{148,149} Atypical melanocytes may develop in pre-existing nevi exposed to ultraviolet light in an experimental situation.¹⁵⁰ PUVA-exposed skin that is without clinically evident lesions may also show melanocytic atypia.¹⁵¹ Many of the lesions are simply freckles without any increase in melanocytes.

SCAR LENTIGO

The development of a pigmented lesion in the surgical scar of a previously excised pigmented lesion can give rise to clinical concern.^{152,153} Similar lesions have also been reported in surgical scars, unrelated to previous nevomelanocytic lesions.¹⁵⁴ In a comparatively recent study,

Figure 32.5 PUVA lentigo showing an increase in basal melanocytes, some of which are large and mildly atypical. (H&E)

three types of clinical pigmentation were observed: lentigo-like lesions, pigmented streaks, and diffuse pigmentation in grafts.¹⁵⁵ It has been suggested that the scar tissue is responsible for the induction of melanocytic hyperplasia and/or hyperfunction.¹⁵⁵

Histopathology

Two different patterns can be seen. In one, there is lentiginous epidermal hyperplasia, hyperpigmentation, and a normal or moderately increased number of melanocytes. In the other, there is melanocytic hyperplasia without accompanying epidermal hyperplasia.¹⁵⁵

MELANOCYTIC NEVI

Melanocytic nevi are occasionally present at birth (congenital melanocytic nevi), but the majority appear in childhood or adolescence (acquired melanocytic nevi).^{156,157} Congenital nevi show some distinct morphological features and are therefore considered separately (see p. 856).

Various studies have been undertaken in recent years to ascertain the prevalence of nevi in certain population groups and the role of environmental factors in their etiology.¹⁵⁸ All of these studies have concluded that sun exposure in childhood predisposes to the development of more nevi, some of which may be larger than usual or have atypical features.^{159–167} It appears that the emergence of nevi in adolescents is under strong genetic control, whereas environmental exposures affect the mean number of nevi.¹⁶⁸ This genetic control does not appear to be related to changes in the *CDKN2A* gene.¹⁶⁹ Nevertheless, some loss of heterozygosity is present in nevi, suggesting that some are precursors of melanoma.¹⁷⁰ Microsatellite instability and other markers of malignancy have also been found in benign nevi.^{171,172} Nevi are more prevalent in boys than girls,¹⁷³ in white children than in other ethnic groups,¹⁵⁹ and in children with fair skin and blond or red hair.¹⁷⁴ This latter finding has been contradicted by a study of 280 three-year-olds. Children with red hair had more freckles but fewer melanocytic nevi than other children of this age.¹⁷⁵ Whereas both immunosuppression and solar radiation are associated with increased numbers of nevi in children, this may not be the case in adults.^{176–183} The use of a sunscreen reduces the development of new nevi on intermittently sun-exposed body sites particularly among freckled children.¹⁸⁴ Sun protection by other means also reduces the nevus burden.¹⁸⁵ In contrast, neonatal phototherapy is a strong risk factor for nevus development in childhood.¹⁸⁶ Experimentally, ultraviolet radiation produces transient melanocytic activation.¹⁸⁷ Fewer melanocytic nevi are found in children with active atopic dermatitis than in children without dermatitis,¹⁸⁸ although this has been disputed.¹⁸⁹ They are also decreased in some patients with chronic cutaneous graft-versus-host disease, but they may show atypical features.¹⁹⁰ Nevi are increased in Turner syndrome.¹⁹¹

Acquired melanocytic nevi undergo progressive maturation with increasing age of the lesion. Initially, the acquired melanocytic nevus is a flat macular lesion (junctional nevus) in which nests of proliferating melanocytes are confined to the dermoepidermal junction. The lesion becomes progressively more elevated as nests of nevus cells extend ('drop off') into the underlying dermis (compound nevus). Unna's concept of *Abtropfung* ('dropping off') has been challenged in recent times,^{192,193} although the higher reactivity of proliferating cell nuclear antigen (PCNA) in junctional and compound nevi than in intradermal nevi supports the epidermal origin of acquired melanocytic nevi.¹⁹⁴ The MDP (melanocyte differentiation pathway) hypothesis is an attempt to explain the origin of melanocytes and their subsequent upward migration into the epidermis – the reverse of *Abtropfung*.^{195,196} This theory has also been applied by Cramer to the formation of the speckled lentiginous nevus.¹⁹⁷ Zalaudek *et al.* put forward another theory

based on dermoscopy that involves neither of these theories of pathogenesis.^{198,199} With further maturation, junctional activity ceases and the lesion is composed only of dermal nevus cells (intradermal nevus). Intradermal nevi usually become progressively less pigmented over the ensuing years. This process of maturation is somewhat variable in duration, but most nevi are intradermal in type by early adult life. It should be remembered that the junctional lentiginous nevus is a common entity in adult life, and it appears that this lesion has mistakenly been used in theories related to the pathogenesis of nevi.¹⁹⁸ However, nevi on the palms of the hands, soles of the feet, and the genital region are often slow to mature, and they remain as junctional nevi for some time. This feature gave rise in the past to the erroneous belief that nevi in these sites were prone to malignant change. Some nevi may increase in size during pregnancy and adolescence,^{200–203} although the extent of this change has been questioned.²⁰⁴ They do not appear to change as a consequence of growth hormone therapy.^{205,206} However, nevi may change in their dermoscopic appearance (and histology) following ultraviolet radiation.²⁰⁷ Uncommonly, nevi change as a consequence of tattooing.²⁰⁸

It has been customary to refer to the cells comprising a melanocytic nevus as 'nevus cells' or 'nevomelanocytes'. Nevus cells are melanocytes that have lost their long dendritic processes, probably as an adaptive response associated with the formation of nests of cells.²⁰⁹ Because this change cannot usually be appreciated in hematoxylin and eosin (H&E)-stained preparations, it has been suggested that all cells in melanocytic nevi (epidermal and dermal) should be referred to as melanocytes.²¹⁰ Many nevi appear to be clonal.²¹¹ Interestingly, the 'maturation' of melanocytes is accompanied by an alteration in the antigens they express. Cells in the junctional layer contain S100 protein and sometimes one or more of the melanoma-associated antigens, including NKI/C3, gp100 (HMB-45), and MART-1. gp100 expression is lost by dermal nevus cells.²¹²

With advancing age, there is a progressive decrease in the number of nevi. Whereas the number of nevi in young adults varies from approximately 15 to 40, this decreases markedly over the age of 50 years.^{213–215} It has been proposed that this occurs by progressive fibrosis of nevi and in some cases by transformation into skin tags that may self-amputate, but others have not confirmed this theory.²¹⁶ Some nevi disappear in adolescence.²¹⁷ The presence of large numbers of nevi is a risk factor for the development of malignant melanoma.^{218,219} Large numbers of nevi are present in some patients with idiopathic scoliosis.²²⁰ Incidental microscopic foci of nevic aggregates occur in the skin, particularly in the head and neck region.²²¹ Knowledge of their occurrence should prevent their misdiagnosis in cases of concurrent melanoma.²²¹

Rarely, multiple nevi may develop in a patient over the course of several months. An underlying bullous disease, including hereditary epidermolysis bullosa, has sometimes been present in these cases of eruptive nevi.^{222–224} They also occur in patients with renal allografts.²²⁵ These post-transplant eruptive nevi may fade after suspension of immunosuppressive therapy.^{226,227} Eruptive nevi have also followed exposure to sulfur mustard gas used in warfare,²²⁸ the administration of 6-mercaptopurine,²²⁹ and the use of biologicals.^{230,231}

It is generally accepted that all biopsied/removed nevi be submitted for histological examination for medicolegal reasons. In one study, 2.3% of clinically diagnosed benign nevi were microscopically diagnosed as malignant tumors, either melanomas or basal or squamous cell carcinomas.²³²

In 2007, a new classification system for nevi was proposed, based on dermoscopic features.^{233,234} The categories included globular (congenital), reticular (acquired), starburst (Spitz/Reed), blue (homogeneous), site-related nevi, and those with special features such as halo, eczematous, combined,²³⁵ and recurrent nevi.²³³ Dermoscopy is a valuable non-invasive method of distinguishing benign and malignant lesions.^{236–239} The dermoscopic appearances of nevi may change after

PUVA or UVB therapy.^{240,241} Dermoscopy can also be used on fixed specimens to guide tissue sectioning in gross pathology.²⁴²

Although the *BRAF* V600E mutation is common in melanomas, it is also found in a significant number of benign nevi.²⁴³ This finding suggests that *BRAF* mutations may be early events in melanoma development (see p. 875).

JUNCTIONAL NEVUS

The junctional melanocytic nevus is a well-circumscribed brown to black macule, which may clinically resemble a lentigo. It may develop anywhere on the body surface. Usually, it appears during childhood or early adolescence, and it matures with time into a compound nevus and later into an intradermal nevus. Junctional nevi may also be found in adults.²⁴⁴ The small 'active junctional nevus' reported by Eng in adolescents has some resemblance to the lesion described earlier as a lentiginous nevus.²⁴⁵ A periorbital lesion with unusual clinical features has been reported.²⁴⁶

Histopathology

The junctional nevus is composed of discrete nests of melanocytes/nevus cells at the dermoepidermal junction, usually located on the rete ridges, which often show some accentuation. The cells are oval to cuboidal in shape, with clear cytoplasm containing a variable amount of melanin pigment (Fig. 32.6). Mitoses are rare or absent. Nests of nevus cells sometimes bulge into the underlying dermis, which may contain a few melanophages and a sparse lymphohistiocytic infiltrate.²⁴⁷

Junctional nevi of the nail matrix are one cause of **longitudinal melanonychia**, a characteristic pattern of pigmentation of nail.^{248–250} This pattern of pigmentation can be produced by lesions that resemble lentigos, ephelides, acanthomas, seborrheic keratoses, and even malignant melanomas.^{251,252} No histology was performed on the longitudinal (and horizontal) melanonychias produced by hydroxyurea.^{253,254} Similar lesions can result from doxorubicin and cyclophosphamide.²⁵³ Longitudinal melanonychia can also occur in Addison's disease.²⁵⁵ No melanocytic proliferation would be expected.

Figure 32.6 Junctional nevus. There are discrete nests of nevus cells at the dermal-epidermal junction. (H&E)

COMPOUND NEVUS

Compound melanocytic nevi are most common in children and adolescents. They vary from minimally elevated lesions to dome-shaped or polypoid configurations. They may be tan or dark brown in color. The term '*pointillist nevus*' has been used for rare nevi with multiple, tiny, dark brown to black dots on a skin-colored background.²⁵⁶ A dysplastic pointillist nevus has also been described.²⁵⁷

Histopathology

Compound nevi have both junctional nests and an intradermal component of nevus cells (Fig. 32.7). Whereas the cells in the upper dermis are usually cuboidal, with melanin pigment in the cytoplasm, deeper cells are often smaller and contain less melanin. Apoptosis is sometimes seen in the deeper cells.²⁵⁸ The nevus cells are arranged in orderly nests or cords. The overlying epidermis may be flat, show some acanthosis, or have a seborrheic keratosis-like appearance, even with horn cysts. These nevi have been called '*keratotic melanocytic nevi*'.²⁵⁹ These papillomatous nevi are more common in females; the nevus cells in this variant often express estrogen-inducible pS2 protein.²⁶⁰

A study in 2005 showed that some of the features used in the diagnosis of melanoma are frequently found in benign melanocytic nevi, including poor circumscription, a predominance of single melanocytes, asymmetry, and irregular confluent nests.²⁶¹ Cytological atypia could also be found in a small number of benign nevi.²⁶¹ Mitoses and necrosis were not found in benign lesions,²⁶¹ but mitoses have been found in benign nevi by others.²⁶²

The *pointillist nevus* (discussed previously) shows discrete, densely pigmented junctional melanocytic nests, isolated dermal pigmented nests, or discrete clusters of melanophages in the papillary dermis.²⁵⁶

A study of *traumatized nevi* showed that parakeratosis, ulceration, dermal telangiectasia, and, less commonly, melanin within the stratum corneum are the usual histological features.²⁶³ Pagetoid spread of melanocytes is usually limited to the site of trauma.²⁶⁴ Mitoses are rare.²⁶³

Ackerman suggested the designation of Unna's nevus for these exophytic papillomatous nevi and designation of Miescher's nevus for the dome-shaped exoendophytic nevi that extend far into the reticular dermis.²⁶⁵ Whereas Unna's nevus is an almost purely adventitial lesion confined to an expanded papillary dermis, and often to the

Figure 32.7 Benign compound nevus with both junctional and dermal nests of nevus cells. (H&E)

Figure 32.8 Genital nevus. Features displayed in this image include loss of cohesion of nevomelanocytes within nests, adnexal involvement, and cytologic atypia manifesting mainly as cell enlargement but with preservation of nuclear:cytoplasmic ratios. (H&E)

Figure 32.9 Nevus from the ear. These lesions often feature poor lateral circumscription, suprabasilar melanocytes, elongation of rete ridges, and a degree of cytologic atypia. (H&E)

perifollicular dermis as well, Miescher's nevus has nevomelanocytes diffusely infiltrating both the adventitial and the reticular dermis in a wedge-shaped pattern.²⁶⁶ It has been suggested that Unna's nevus is a 'tardive congenital nevus'.²⁶⁷

Site-specific variations

Benign melanocytic nevi in certain anatomical sites may show unusual histopathological features.²⁶⁸ The best known of these are nevi of the vulva and acral region. Nevi in other sites, such as the ear, breast, scalp, and flexural locations, may show similar features.²⁶⁹ Nevi on the distal lower extremity (ankle) are the latest group of atypical nevi to be delineated.²⁷⁰

Some vulvar nevi in premenopausal women show atypical histological features characterized by enlargement of junctional melanocytic nests, with variability in the size, shape, and position of the nests.²⁷¹⁻²⁷³ Pagetoid spread of melanocytes is often present.²⁷⁴ These atypical lesions have been called *atypical melanocytic nevi of the genital type*.^{275,276} In one study of six cases, no recurrences were recorded on long-term follow-up.²⁷⁵ Other changes described for genital nevi may include loss of cohesion of melanocytes within nests, adnexal involvement, atypia in terms of cellular enlargement but with preserved nuclear-to-cytoplasmic ratios, and rare mitoses (Fig. 32.8).^{276,277} In a study of 56 cases, only one lesion had recurred on follow-up, but no further recurrence of this lesion had occurred 11 years after its re-excision.²⁷⁷ Nevi in pregnant women may also show some 'activation', with an increase in basal melanocytes and an increase in mitotic activity in these cells.²⁷⁸ The changes are usually mild and never of sufficient degree to result in diagnostic confusion.²⁷⁸

Nevi from the *auricular region* may also show atypical features. The author has received, for a second opinion, the histology slides of many atypical nevi removed from the ears of adolescent males. These atypical nevi may also arise in females. They often show poor circumscription, lateral extension of the junctional component beyond the dermal component, and elongation of rete ridges with bridging between them.²⁷⁹ Pagetoid spread and cytological atypia may also be present (Fig. 32.9).²⁸⁰ Mitoses and apoptotic nevomelanocytes are rare. Many cases show a mild lymphocytic infiltrate.²⁸⁰

Nevi from the *breast* also show atypical features, in both males and females.²⁸¹ Mild pagetoid spread, melanocytic atypia, and dermal

Figure 32.10 Conjunctival nevus. Goblet cells (arrows) and pseudoglandular spaces can be identified among densely aggregated nevomelanocytes. There is a degree of cytologic atypia that is not unusual for melanocytic nevi in this location. (H&E)

fibroplasia are sometimes found.^{276,281} A garland-like arrangement of junctional nests has been described.²⁷⁶

Flexural nevi may show a nested and dyshesive pattern with some variability in nest size and arrangement.²⁸²

Conjunctival nevi are another example of nevi at special sites that may present with worrisome features (Fig. 32.10).^{276,283} To expand upon information discussed in Chapter 2 (p. 32), two of the authors (DW and JWP) have always accepted the advice given to them more than 35 years ago that it was safe to 'downgrade' the atypia that is often seen in conjunctival nevi. Conjunctival nevi need to be distinguished from conjunctival melanosis in which there is increased pigmentation or a mild increase in normal melanocytes.²⁸⁴ Atypia of these melanocytes can also be present. This subject was reviewed in 2007.²⁸⁴

Figure 32.11 Acral nevus. Upward intraepidermal migration of nevomelanocytes is noted in this example. (H&E)

Melanocytic lesions of the *palms and soles* may also cause diagnostic difficulties.²⁸⁵ This appears to be related, in part, to the presence of skin markings (dermatoglyphics) in these sites.^{286–288} If sections are cut perpendicular rather than parallel to the dermatoglyphics, symmetry and circumscription are seen more often.²⁸⁶ McCalmont *et al.* have drawn attention to the difficulty in diagnosing acral nevi showing some pagetoid spread. They coined the term ‘MANIAC’ (*melanocytic acral nevi with intraepidermal ascent of cells*) for such lesions.²⁸⁹ This is an example of pagetoid melanocytosis – a process seen in many nevi at special sites (**Fig. 32.11**).²⁶⁴ Dermoscopic features of acral nevi appear to be variable, and they may change with short-term follow-up.^{290–292} The changes appear to reflect the unique anatomical and histopathological characteristics of acral skin.^{293–295} Agminated nevi of the sole are exceedingly rare.²⁹⁶ Eruptive nevi have also been reported.²⁹⁷ Subungual nevi are sometimes included in this category of atypical nevi of the palms and soles.²⁹⁸ Transepidermal elimination of well-circumscribed nests of nevus cells is sometimes seen in benign nevi, but pagetoid infiltration of the epidermis by single atypical cells, or small groups of atypical cells with pale cytoplasm, should be viewed with suspicion.^{274,299,300} A lymphocytic infiltrate in the dermis is suspicious but not diagnostic of melanoma.²⁹⁹ There is a unique variant of nevus on plantar skin – acral lentiginous nevus.³⁰¹ The appearances in this lesion have some resemblance to a dysplastic (atypical) nevus, although they lack cytological atypia and lamellar fibroplasia.³⁰¹

Nevi on the *scalp* of adolescents may show atypical features, but they apparently behave in a benign manner after complete excision.³⁰² Approximately 10% of nevi removed from this site at one institution showed atypical features.³⁰² There were large, bizarrely shaped nests scattered in a disorderly manner along the junctional zone; follicular involvement; some pagetoid spread and mild cytological atypia. There were some ‘discohesive melanocytes’ in the junctional nests.³⁰²

Nevi on the *distal lower extremity (ankle)* may have moderate to severe architectural atypia but only mild to moderate cytological atypia.²⁷⁰ As such, they share features with acral nevi, dysplastic nevi, and melanoma *in situ*.²⁷⁰ The median age of the patients in the study was 47 years. They were treated with simple excision. There has been no recurrence. The authors admitted that these lesions might be early dysplastic nevi. They also stated that although they might be grouped with other acral nevi, their distinctive features warranted separate consideration.²⁷⁰

Another special group of nevi are the *nail matrix* nevi.³⁰³ Most are junctional in type, but when compound there is usually little maturation of cells in the dermis. The distribution of melanocytes in the basal layer may not be symmetrical. Pagetoid spread of melanocytes is confined to the suprabasal layer. The lesions present clinically as longitudinal melanonychia.³⁰³

Divided or ‘kissing’ nevi are compound or intradermal nevi found usually on the eyelids, but they may also occur on the penis and vulva.³⁰⁴ They are thought to develop during embryogenesis as a consequence of the separation of originally joined structures.

INTRADERMAL NEVUS

Intradermal nevi are the most common type of melanocytic nevi. The vast majority are found in adults. They are usually dome-shaped, nodular or polypoid lesions that are flesh-colored or only lightly pigmented. Coarse hairs may protrude from the surface. Rare clinical variants have had a lobulated³⁰⁵ or cerebriform appearance.^{306,307} The cerebriform variant may produce secondary cutis verticis gyrata if it occurs on the scalp.^{308,309}

Nevi are sometimes removed for cosmetic reasons or because they are constantly irritated by clothing or shaving. Reactivation, regression, inflammation, or rupture of a hair follicle within a nevus may all lead to their removal. Shave excision has many advantages over complete surgical excision; it also produces excellent cosmetic results.³¹⁰

Histopathology

Nevus cells are confined to the dermis, where they are arranged in nests and cords. Intradermal nevi commonly show intranuclear pseudo-inclusions that are cytoplasmic invaginations within the nuclei of nevus cells. True intranuclear inclusions are extremely rare.³¹¹ In one case with prominent eosinophilic intranuclear inclusions, they were thought to represent the aftermath of an infection with molluscum contagiosum.³¹² Multinucleate nevus cells may be present. In the deeper parts of the lesion, the nevus cells may assume a neuroid appearance (‘neural nevus’, neurotized melanocytic nevus), with spindle-shaped cells and structures resembling Meissner’s tactile body (**Fig. 32.12**). Apoptotic cells are not present in neurotized intradermal nevi.³¹³ Verocay-like bodies reminiscent of a neurilemmoma have also been reported.³¹⁴ These various patterns may represent different expressions of peripheral nerve sheath differentiation.³¹⁵

These neuroid cells are quite distinct with electron microscopy and immunohistochemistry from those seen in a neurofibroma.^{316,317} The cells in a neurofibroma show focal staining for Leu7, glial fibrillary acid protein (GFAP), and myelin basic protein (MBP) – antigens not expressed in neurotized melanocytic nevi.³¹⁶ Neither cell expresses peripherin, an intermediate filament found in neurons and some melanomas.^{318,319} However, nerve growth factor receptor expression is increased in neural nevi,³²⁰ and S100A6 stains the Schwann cell-like type C cells.³²¹ With increasing age of the lesion, there may also be replacement of nevus cells within the dermis by collagen, fat,³²² elastin, and ground substance.²¹⁶ Mucin deposition was present in 2.75% of intradermal nevi in one study.³²³

Electron microscopy

The ultrastructural features of nevus cells are similar to those of melanocytes, although they lack the long dendritic processes of the melanocyte. Instead, they have microvillous processes. The cells contain abundant cytoplasmic organelles, including melanosomes.³²⁴

Secondary changes in nevi

Many interesting changes may be found in nevi.³²⁵ They include the incidental finding of amyloid³²⁶ or of bone (osteonevus of Nanta),³²⁷ epidermal spongiosis producing a clinical eczematous halo

Figure 32.12 (A) Intradermal nevus with stromal fat. **(B)** Some nevus cell nests have a neuroid appearance. (H&E)

– Meyerson’s nevus (see later);^{328–332} the concurrence of psoriasis;³³³ increased amounts of elastic tissue;³³⁴ nodular myxoid change;³³⁵ cystic dilatation of related hair follicles;³³⁶ folliculitis;³³⁷ epidermal, dermoid, or trichilemmal cyst formation,^{338,339} sometimes with rupture, producing sudden clinical enlargement; psammoma body formation;³⁴⁰ sebocyte-like melanocytes;³⁴¹ granular cell change;^{342,343} granulomatous inflammation in regressing lesions;³⁴⁴ paramyxovirus-like inclusions;³⁴⁵ perinevoid alopecia;³⁴⁶ focal epidermal necrosis;³⁴⁷ an incidental molluscum contagiosum;³⁴⁸ and an associated trichoepithelioma,³⁴⁹ basal cell carcinoma,³⁵⁰ syringoma,³⁵¹ or sweat duct proliferation.^{325,352} Artifacts may be caused by paraffin processing or by the injection of local anesthetic.³⁵³ In the latter instance, there is separation of nevus cells into parallel rows. Changes associated with tissue processing include the formation of clefts and spaces resembling vascular or lymphatic channels. The cells lining these pseudovascular spaces have been identified as nevus cells by immunoperoxidase studies using various markers.³⁵⁴

Mitoses may also occur in conventional melanocytic nevi. They were found in 7 of 157 nevi (4%) in one study. In all but one case, the mitosis was present in the papillary dermis.²⁶²

Tiny foci of hyperpigmentation (‘small dark dots’) may develop in nevi. The increased pigment may be in epidermal melanocytes, melanophages, or dermal nevus cells. The heavily pigmented foci sometimes correspond to circumscribed nodules of atypical epithelioid cells – **clonal nevi**.^{355,356} Clonal nevi have also been called inverted type A nevi

Figure 32.13 (A) Clonal nevus. **(B)** There is a small focus of heavily pigmented nevus cells with pale cytoplasm within a nevus. (H&E)

or have been regarded as a variant of combined nevus or superficial deep penetrating nevus.^{357–359} The cells possess fine dusty melanin pigment and often have an irregular nuclear contour (Fig. 32.13). There are stromal melanophages. The nevus cells are often HMB-45⁺.³⁶⁰ The appearances differ slightly from an epithelioid Spitz nevus. Rarely, the ‘small dark dots’ represent melanoma change.³⁶¹ Dermoscopic assessment may assist in the clinical diagnosis of acquired melanocytic nevi with eccentric foci of hyperpigmentation (‘Bologna sign’).³⁶²

Perifollicular hypopigmentation results from a variety of histological changes, including reduced numbers of nevomelanocytes and decreased pigmentation of keratinocytes, in the follicular region.³⁶³ It may lead to variegate pigmentation and an irregular border to the nevus.

Large acquired melanocytic nevi occur in patients with many different types of epidermolysis bullosa.³⁶⁴ These **EB nevi** have a clinical and dermoscopic resemblance to melanoma.³⁶⁵ They are benign. The histopathological patterns of these nevi range from a banal congenital pattern to the persistent/recurrent pseudomelanoma pattern.³⁶⁵

The presence of mycosis fungoides superimposed on a nevus is rare and may lead to confounding histological features or the development of the halo nevus phenomenon.³⁶⁶

MEYERSON NEVUS

The Meyerson nevus is a junctional, compound, or intradermal nevus surrounded by an eczematous halo that may be pruritic.^{328,331,367} The change may involve one or more nevi simultaneously. It occurs more often in young adults than in children.³³² Unlike the halo nevus, Meyerson nevus does not undergo regression as a consequence of this change; however, the evolution of a Meyerson nevus into a halo nevus has been reported.^{368,369} Vitiligo also developed in one such patient.³⁶⁹ The nature of the process is uncertain, but resolution of the eczematous halo has followed the excision of the central nevus alone. Multiple Meyerson nevi appeared in a patient with Behçet syndrome and the dysplastic nevus syndrome when the dosage of interferon (IFN)- α -2b was increased.³⁷⁰ They have also followed the use of IFN- α -2b and IFN- α -2a, used with ribavirin in the treatment of hepatitis C infection.^{371,372}

An eczematous halo (the Meyerson phenomenon) has also been reported around dysplastic (atypical) nevi,³⁷³ a lesion of molluscum contagiosum, and obscuring a nevus flammeus.³⁷⁴

The striking seasonal occurrence of this entity (late winter/early spring) and the pityriasiform spongiosis have led some to speculate that it is due to a nevtropic herpesvirus.

Surgical excision or shave biopsy is the usual method of treatment for solitary lesions. If multiple lesions are present, topical corticosteroids can be used to treat the eczematous halo.³⁷⁵

Histopathology

There is a subacute spongiotic dermatitis associated with a nevocellular nevus (Fig. 32.14). The spongiosis is often of pityriasiform subtype. Eosinophils are usually present in the cellular infiltrate, and they may show exocytosis into the epidermis. There is no regression of the nevus.

ANCIENT NEVUS

Some nevi, particularly from the face of older individuals, can show a degree of cytological atypia that may lead to the erroneous diagnosis of malignant melanoma.^{376,377} Clinically, the lesion is usually a dome-shaped, skin-colored or reddish brown papule or nodule. In a study of 13 patients with ancient nevus by Kerl *et al.*, there was no evidence

Figure 32.14 Meyerson nevus. Spongiotic (eczematous) changes superimposed on a benign compound nevus. Clinically, the lesion had recently developed an 'eczematous halo'. (H&E)

of recurrence or metastasis over a median follow-up of 9 years.³⁷⁸ Ancient nevus is a rare simulator of melanoma on dermoscopy.³⁷⁹

Histopathology

Most lesions are intradermal in type, although there is sometimes a junctional component. One population of dermal nevomelanocytes has large pleomorphic nuclei, whereas the other has small monomorphous ones (Fig. 32.15).³⁷⁶ The large melanocytes may resemble those of the epithelioid variant of Spitz nevus. The smaller, monomorphous cells are sometimes arranged in a congenital nevus pattern.³⁷⁸ Occasional mitotic figures may be present, but there has been a low labeling index with Ki-67.³⁷⁸ Degenerative changes such as thrombi, hemorrhage, sclerosis around dilated venules, stromal fibrosis, and mucin are usually present.³⁷⁹

REACTIVATED NEVUS

This neglected entity is not uncommon in clinical practice. It is characterized by change, often focal, in a nevus of long standing. Usually there is focal darkening of the nevus. It may be mistaken for melanoma

Figure 32.15 Ancient nevus. One population of cells is large with hyperchromatic nuclei. (H&E)

Figure 32.16 Reactivated nevus. Focal junctional activity overlies a banal intradermal nevus in this 40-year-old female. (H&E)

change in a nevus. Reactivation occurs occasionally in pregnancy. Chan *et al.* examined nevi from 16 pregnant women and compared them with those of age-matched nonpregnant control patients.³⁸⁰ They noted a comparative increase in mitoses and the proliferative index by Ki-67 in the nevi from pregnant women. They also described a distinctive histologic feature in these nevi that they termed superficial micronodules of pregnancy (SMOPs).³⁸⁰ Other studies have reported no impact of pregnancy on nevi.³⁸¹

Histopathology

Usually there is focal junctional activity overlying a banal intradermal nevus (Fig. 32.16). Often, there are a few nests of more heavily pigmented nevus cells in the upper dermis beneath the renewed junctional activity. When junctional activity ceases, pigmented nevus cells remain in the upper dermis. They contrast with the nonpigmented nevus cells of the pre-existent nevus.

DEEP PENETRATING NEVUS

The deep penetrating nevus (plexiform spindle cell nevus) is a variant of melanocytic nevus found on the face, the upper part of the trunk, and the proximal part of the limbs of young adults.³⁸² Multiple lesions in a linear arrangement have been described.³⁸³ It is often deeply pigmented, with some variegation in color, leading to a mistaken clinical diagnosis of blue nevus or malignant melanoma. There are also histological features that overlap with these two entities and with the Spitz nevus. Deep penetrating nevi have been regarded as a variant of congenital nevus.

In a series of 31 cases published in 2003, there was an age range between 3 and 56 years.³⁸⁴ Only 1 case, with some atypical histological features, recurred locally after excision. No lesion metastasized.³⁸⁴ The lesions ranged in size from 2 to 10 mm.

Histopathology³⁸²

The deep penetrating nevus is usually of compound type, but the junctional nests are only small in most cases. It may have a wedge shape on low power, with the apex of the wedge directed toward the deep dermis.^{385,386} The lesion is composed of loosely arranged nests and fascicles of pigmented nevus cells, interspersed with melanophages.³⁸⁴ Spindle cells are the predominant cell type, but varying numbers of

Figure 32.17 Deep penetrating nevus. Nests of nevus cells extend into the deep reticular dermis. (H&E)

epithelioid cells are also present.³⁸⁵ The nests extend into the deep reticular dermis and often into the subcutaneous fat (Fig. 32.17). They surround hair follicles, sweat glands, and nerves. Pilar muscles are sometimes infiltrated.

Although there is some pleomorphism of the nuclei of the nevus cells, nucleoli are generally inconspicuous and mitoses are rare. Nuclear vacuoles and smudging of the chromatin pattern are additional features. A superficial variant of deep penetrating nevus has been recognized. It shows overlap features with the epithelioid blue nevus (see p. 860).³⁸⁷ It has been suggested that the melanocytic nevus with focal atypical epithelioid components (clonal nevus; see p. 846) is a superficial variant of deep penetrating nevus,³⁸⁹ but subsequent correspondence from Murali *et al.* stated that such lesions were combined nevi.³⁸⁸

Immunohistochemical studies have shown that the cells express S100 protein and gp100 (HMB-45).^{385,386,388} PCNA is present in only scattered melanocytes (<5%) in the deep penetrating nevus, whereas 25–75% of the cells in a melanoma will usually stain.³⁸⁹

Differential diagnosis

Features occurring in deep penetrating nevus that raise concerns for melanoma include some asymmetry, a degree of nuclear pleomorphism, a lack of maturation descent, occasional dermal mitoses, and patchy dermal inflammation.³⁹⁰ However, in deep penetrating nevi there is discontinuity between the junctional component (present in the majority of cases) and the area of dermal involvement, with sparing

of the papillary dermis (unless there is also a conventional nevus component, in which case ordinary nevus cells are present in the epidermis and papillary dermis).³⁹⁰ Melanomas often have a greater degree of asymmetry and poor circumscription of the junctional component, expansile nests, more pronounced cytologic atypia, and frequent mitoses.³⁹⁰ Pigment-synthesizing melanomas may have a dendritic junctional component, and although there is proliferation along adnexa (a feature of deep penetrating nevus), dermal growth is both more diffuse and destructive – often with infiltration into the subcutis.³⁹⁰

Deep penetrating nevi and plexiform spindle cell nevi share some microscopic features with Spitz nevus and cellular blue nevus, although they can generally be distinguished from these nevi by their typical clinical presentation and wedge-shaped or plexiform configuration. They also lack the bland-appearing, scattered, pigmented dendritic cells and (often) the degree of sclerosis of blue nevi or the bundles of nonpigmented cells with ovoid nuclei seen in cellular blue nevi. There has been a recent case of primary cutaneous clear cell sarcoma, with epidermal involvement, that mimicked a Spitz nevus but eventually metastasized to a regional lymph node. The diagnosis was made when cytogenetic analysis of the metastatic tumor showed a t(12;22) translocation, and FISH analysis using a break-apart probe for the Ewing's sarcoma breakpoint region 1 showed rearrangement in the majority of tumor cells.³⁹⁰

BALLOON CELL NEVUS

The balloon cell nevus is a rare lesion that is clinically indistinguishable from an ordinary melanocytic nevus. A depigmented halo has rarely been described.³⁹¹

Histopathology

The balloon cell nevus is composed of somewhat swollen nevus cells, with clear cytoplasm and a central nucleus that appears comparatively hyperchromatic (Fig. 32.18). Multinucleate balloon cells are often present. Apoptosis involving isolated balloon cells has been reported.³⁹² The diagnosis should be restricted to lesions containing a preponderance of balloon cells (>50%) and not applied to nevi showing only a few foci of balloon cell change.³⁹³ Balloon cell change has also been reported in dysplastic (atypical) nevi.³⁹⁴

Electron microscopy

The balloon cells appear to form by the progressive vacuolization of nevus cells resulting from the enlargement and eventual destruction of melanosomes.³⁹⁵

Differential diagnosis

Balloon cell melanomas have also been described (see p. 884). The cells have larger nuclei than those in the balloon cell nevus, and mitoses can usually be found in the dermis. Balloon cell change can also involve nodal melanocytic nevi (nodal balloon cell nevus).³⁹⁶

HALO NEVUS

A halo nevus is characterized by the presence of a depigmented halo up to several millimeters in width around a melanocytic nevus. This change is most often an idiopathic phenomenon that precedes the lymphocytic destruction of the nevus cells and the clinical regression of the lesion.^{397,398} Note that the lymphocyte-mediated regression of a nevus can take place without the development of a clinical halo.³⁹⁹ Conversely, the clinical halo phenomenon may not be accompanied by inflammation on histologic examination. Halo change may involve one or several nevi. Halo nevi of the choroid are described in the ophthalmology literature.⁴⁰⁰ Very rarely, a halo may develop around a

Figure 32.18 (A) Balloon cell nevus. (B) Many of the cells have clear cytoplasm. (H&E)

congenital melanocytic nevus or a nodular melanoma.^{401,402} Another rare phenomenon is the development of a targetoid halo.⁴⁰³ This may consist of an annular pigmented ring with a central pale brown to grayish zone.⁴⁰⁴ The 'golden brown halo' found on dermoscopy of a Miescher nevus⁴⁰⁵ and the cockarde nevus (see later) may be related phenomena. Familial cases have been reported.⁴⁰⁶ Halo nevi also occur in Turner syndrome. A putative halo nevus susceptibility gene is located close to the HLA-C locus.⁴⁰⁷ Localized leukotrichia was also present in one case.⁴⁰⁸

An unusual inflammatory and hyperkeratotic variant of halo nevus has been reported in 14 children from Bologna, Italy.⁴⁰⁹ All nevi showed the same clinical development. After an initial inflammatory stage, their surfaces gradually became thickened and rough, then verrucous and raised, and finally scaly and crusted. A marked halo of depigmentation subsequently developed in all lesions, with simultaneous disappearance of the hyperkeratotic surface.⁴⁰⁹ The histology was typical of a halo nevus with variable epidermal hyperplasia.⁴⁰⁹ Another unusual variant is the pseudo-halo nevus produced by the application of sunscreen to a nevus and its immediate surroundings.⁴¹⁰

Circulating antibodies that react against melanoma cells have been found in a high proportion of individuals with halo nevi, as have circulating lymphocytes with an activated phenotype,⁴¹¹ suggesting that both humoral and cell-mediated immunity are involved in the rejection of nevus cells and the formation of the halo (see later).⁴⁰²

The halo nevus must be distinguished from the Meyerson nevus (see p. 847), in which there is an eczematous halo surrounding a nevus.

Halo nevi exhibit the characteristic dermoscopic features of benign melanocytic nevi, represented by globular and/or homogeneous patterns.⁴¹² There is considerable size reduction of the nevus component with time.⁴¹²

Histopathology

There is usually a dense lymphocytic infiltrate within the dermis, with nevus cells surviving in nests or singly among the lymphocytes. The number of nevus cells will, of course, depend on the stage at which the biopsy is taken. Surviving nevus cells may appear slightly swollen, with some variation in size, and these changes may be worrisome. In one study, 51% of lesions showed cells with some degree of atypia, ranging from minimal to moderate severity.³⁹⁸ However, a heavy diffuse infiltrate of lymphocytes of the type seen in halo nevi is most unusual in a malignant melanoma. Macrophages are also present in the infiltrate. Granulomatous inflammation has also been described in regressing nevi with and without a depigmented halo.³⁴⁴ Rarely, a halo nevus is devoid of inflammatory cells.⁴¹³ Regression would not occur in such cases. Fibrosis does not occur in the dermis as a consequence of the regression that occurs in a halo nevus, whereas it does occur following melanoma regression.⁴¹⁴ This difference may result from the higher expression of the antifibrotic cytokine tumor necrosis factor- α (TNF- α) in halo nevi than in regressing melanomas.⁴¹⁴ Nevertheless, thin, wispy fibroplasia parallel to the surface does occur in the papillary dermis at the edges of halo nevi.⁴¹⁵ Immunohistochemical staining for the presence of S100 protein (or MART-1) may assist in the identification of residual nevus cells in cases in which a dense inflammatory infiltrate tends to obscure the nature of the lesion.⁴¹⁶ Immunohistochemistry has also been used to characterize the nature of the lymphocytes present in the dermis. They are mostly CD8⁺ T lymphocytes that express the activation molecule CD69 as well as TNF- α .^{417,418} Macrophages and factor XIIIa⁺ dendrocytes are also found in the infiltrate.⁴¹⁹

The depigmented halo shows an absence of melanin pigment and melanocytes in the basal layer. Lymphocytes are sometimes noted in close proximity to residual melanocytes in the halo zone of newly forming lesions, but they are not usually present in the basal layer of established lesions. In one case, the adjacent epidermis showed interface changes resembling erythema multiforme with keratinocytes targeted by lymphocytes.⁴²⁰

Based on the description of one case, the targetoid halo nevus displays elongated rete ridges, nest formation, and an underlying inflammatory infiltrate containing melanophages at the lesional borders, with increased junctional melanocytes, although to a lesser degree and without nesting, in the central portion of the lesion.⁴⁰⁴

Electron microscopy

Ultrastructural studies have shown nonspecific injury changes in some nevus cells and destruction of others.^{421,422} It seems likely that the nevus cells die by the process of apoptosis, but this requires confirmation.

COCKARDE NEVUS

The term 'cockarde nevus' (cocarde nevus, cockade nevus) refers to nevi that develop a peripheral pigmented halo with an intervening zone that is nonpigmented.⁴²³⁻⁴²⁵ Several cases have been reported in association with spinal dysraphism.⁴²⁶ A cockarde nevus has been reported in association with multiple **eclipse nevi**, a lesion characterized by a tan center and an irregular darker brown peripheral rim that is occasionally discontinuous.^{427,428}

Histopathology

The central nevus is of junctional or compound type, whereas the peripheral halo is usually composed of junctional nests. The intervening nonpigmented zone is usually devoid of nevus cells.

ECCRINE-CENTERED NEVUS

The eccrine-centered nevus is a rare variety of nevocellular nevus in which the nevus cell proliferation is closely related to eccrine sweat ducts.⁴²⁹

RECURRENT NEVUS

Nevi may recur following shave biopsy of the lesion, with or without electrodesiccation.^{430,431} Because the histological features of these recurrent nevi may be worrisome, Kornberg and Ackerman coined the term 'pseudomelanoma' for them.⁴³² However, because only a minority of such lesions mimic melanoma histologically, it has been suggested that this term be dropped.⁴³³ Their appearances on dermoscopy may cause difficulties in diagnosis.⁴³⁴ Recurrent nevi are not uncommon following inadequate excision of dysplastic (atypical) nevi.⁴³⁵ Sometimes a history of a preceding operation is not provided when this subsequent material is submitted for examination.⁴³⁶ This phenomenon can also be seen after non-biopsy trauma such as chronic irritation⁴³⁷ and laser therapy.^{438,439} Recurrent (persistent) Spitz nevi have also been described (see later).⁴⁴⁰ Dermoscopy may assist in the assessment of melanotic pigmentation in excision scars of melanocytic tumors.⁴⁴¹

Histopathology

These recurrent nevi show a lentiginous and junctional epidermal component (**Fig. 32.19**). Although there may be some upward epidermal spread of the tumor cells, the lesion is sharply circumscribed and there is no lateral extension of melanocytes beyond the dermal scar. There is usually dermal fibrosis resulting from the previous procedure, and nests of mature nevus cells may be found in the dermis deep to, or at the edge of, the scar tissue.⁴³² Within the scar tissue are scattered nevus cells, which resemble fibroblasts on light microscopy.⁴⁴² Melanophages are also increased in the papillary dermis.⁴⁴³

Figure 32.19 Recurrent nevus. There is pagetoid spread of melanocytes overlying a dermal scar. (H&E)

Differential diagnosis

The differential diagnosis of recurrent nevus includes atypical nevus with stromal fibroplasia, melanoma with regressive changes, and recurrent melanoma. A history of a recent surgical procedure at the site, confinement of the lesion to a zone overlying the dermal scar, and careful assessment of the cytologic features should lead to a correct diagnosis. However, caution should be advised, especially when assessing a possible recurrent blue nevus or Spitz nevus, because these do not always ‘obey the rules’ (i.e., extension beyond the confines of the scar or nodular recurrences). Immunohistochemistry shows that junctional melanocytes in recurrent nevi express greater amounts of HMB-45 than the melanocytes in the original lesion.⁴⁴⁴ However, there is a ‘maturation pattern’ with HMB-45,⁴⁴³ whereas in melanoma, there is strong HMB-45 positivity in both the junctional and the deeper dermal portions of the lesion.⁴⁴⁵ As is true for original melanocytic nevi, recurrent nevi show a maturation pattern with both tyrosinase and Ki-67 labeling; Ki-67 labeling of the junction is less than 5%. In contrast, melanomas show tyrosinase expression throughout the entire lesion and, often, higher junctional proliferative activity.⁴⁴⁵ Significant problems can also arise when attempting to distinguish recurrent nevus from recurrent melanoma.⁴⁴⁰ Confirmation of prior biopsy, evaluation of the initial biopsy specimen when possible, and assurance of complete removal of the recurrent lesion are therefore recommended.

SCLEROSING NEVUS

Sclerosing nevus is a recently delineated variant of nevus characterized clinically by a central area of scarring and histologically by striking architectural alteration of the melanocytic component, but with no cytological atypia or mitotic activity.⁴⁴⁶ None of the cases has recurred or metastasized.

The origin of the scar is obscure, but it is probably related to minor unnoticed trauma or to chronic friction. In a few cases, the fibrosis is probably the result of partial regression of the nevus or a sequel to folliculitis. A sclerosing cellular blue nevus has also been described, with dermoscopic features (whitish scar-like area, pigmented dot pattern, and linear irregular vessels) simulating melanoma.⁴⁴⁷

Histopathology

The lesion has a striking resemblance to the so-called recurrent nevus (discussed previously) and the nevi developing on lesions of lichen sclerosus (see p. 363).⁴⁴⁶ Above the dermal scar, there are large, confluent, and unusually shaped melanocytic nests at the dermoepidermal junction and in the dermis. There is pagetoid spread of melanocytes above the scar, similar to a recurrent nevus. There are remnants of nevus at the edge of the scar.⁴⁴⁶ In almost all cases, the cells in the uppermost portion of the lesion express HMB-45 and Ki-67.⁴⁴⁶

Differential diagnosis

Distinction between sclerosing nevus and recurrent nevus includes the finding of atypical melanocytic nests throughout the scarred area in the former (rather than confinement of nests to the uppermost portions of the dermis) as well as the lack of a prior history of biopsy or trauma. HMB-45 and Ki-67 expression is similar to that for recurrent nevus.⁴⁴⁵

SPITZ NEVUS

The eponymous designation ‘Spitz nevus’ is the preferred term for the variant of nevocellular nevus that has also been known in the past by the terms ‘spindle cell nevus’, ‘epithelioid cell nevus’, ‘nevus of large spindle and/or epithelioid cells’, and ‘benign juvenile melanoma’.^{347,448,449} This title recognizes the important contribution of Sophie Spitz, who

for the first time, in 1948, published criteria for the diagnosis of a specific lesion of childhood that, despite some histological resemblance to malignant melanoma, was known to behave in a benign manner.^{450–452}

The typical Spitz nevus is a pink or flesh-colored papule or nodule arising on the face, trunk, or extremities,^{453,454} particularly the lower limbs, of children or young adults. They are uncommon in darkly pigmented children.⁴⁵⁵ Among Hispanic patients, Spitz nevi most often present as pigmented papules on the lower extremities, regardless of sex or age.⁴⁵⁶ Pigmented variants and lesions in other sites or in older individuals are not uncommon.⁴⁵⁷ The tongue is a rare site.⁴⁵⁸ In one published series of 247 cases from Italy, approximately two-thirds of the patients were older than 20 years of age.⁴⁵⁹ Pigmented lesions accounted for 71.7% of cases in one study.⁴⁶⁰ The halo phenomenon has been observed in several cases.⁴⁶¹ Most lesions are less than 1 cm in diameter and solitary, but multiple Spitz nevi have been described in a clustered (agminate) or disseminated pattern.^{462–474} Spitz nevus with multiple satellite lesions is a related entity.⁴⁷⁵ Rare clinical variants include congenital onset,^{476,477} the presence of multiple lesions with intervening (background) hyperpigmentation,^{478–480} development within a speckled lentiginous nevus,^{481–483} and the development of a large nodule following attempted removal.⁴⁸⁴ Painful lesions are rare.⁴⁸⁵ Clinical diagnostic accuracy can be increased by the use of epiluminescence microscopy, but there are still many diagnostic pitfalls.^{486–488} They are often clinically misdiagnosed as pyogenic granuloma, hemangioma, dermatofibroma, or an ordinary nevus.⁴⁸⁹

HRAS mutations and/or 11p gains (HRAS resides on 11p) are observed in 10–29% of Spitz nevi. BRAF V600E or NRAS mutations in Spitz nevi are considered unusual (see later).^{490–492}

Spitz nevi account for approximately 0.5–1% of surgically excised nevi in children and adolescents.⁴⁴⁹ There is a low recurrence rate, even after incomplete excision.^{493–495} Rarely, satellite lesions may occur in recurrent lesions.⁴⁹⁶ Comparative genomic hybridization studies of recurrent lesions suggest that Spitz nevi with an 11p gain may be more apt to recur.⁴⁹⁵ Involution seems to occur in some lesions.⁴⁹⁷

Cramer applied the MDP hypothesis to Spitz nevi. He suggested that relatively impaired melanocyte–keratinocyte interactions in Spitz nevi may contribute to lack of dark pigmentation and to relatively accelerated accumulation of dermal nevus cells.¹⁹⁶

Ideally, all Spitz nevi should be completely excised.^{498,499} The management of atypical Spitzoid tumors is controversial (see later).

Histopathology

The majority of Spitz nevi are compound in type, although 5–10% are junctional and 20% are intradermal lesions. The diagnosis depends on the assessment of a constellation of histological features (Table 32.1), some of which are more important than others.^{449,500–504} Molecular studies are now available for challenging borderline lesions (see p. 890). The major histomorphologic diagnostic criteria include the cell type, the symmetrical appearance of the lesion, maturation of nevus cells, the lack of pagetoid spread of single melanocytes, and the presence of coalescent eosinophilic globules (Kamino bodies). These features are discussed in further detail here.

A Spitz nevus may be composed of either epithelioid or spindle cells, with the latter type being much more common. In one large study, spindle cells only were found in 45% of lesions, spindle and epithelioid cells in 34%, and epithelioid cells only in 21%.⁵⁰⁵ Sometimes the spindle cells are quite plump (Fig. 32.20). On low-power magnification, Spitz nevi are usually quite symmetrical in appearance, with no lateral extension of junctional activity beyond the limits of the dermal component (Fig. 32.21). One study suggested that this is an ‘unsupportable criterion’ for distinguishing a Spitz nevus from a melanoma,⁵⁰⁶ although subsequent correspondence has disputed this assertion.⁵⁰⁷ There is usually ‘maturation’ of nevus cells in depth; this refers to the presence of cells in the deeper parts of the lesion that are smaller and resemble ordinary nevus cells. It has been suggested,

Table 32.1 Diagnostic criteria for Spitz nevi	
Major criteria	Minor criteria
Symmetry	Junctional cleavage
Cell type – epithelioid and/or spindle cells	Superficial multinucleate nevus cells
Maturation of cells	Perivascular inflammation
Absent pagetoid spread of single melanocytes	Absence of nuclear pleomorphism
Coalescent, pale pink Kamino bodies	No deep atypical mitoses
	Deep outlying, solitary nevus cells
	Superficial edema, telangiectasia
	Low AgNOR score
	Stratification of HMB-45 staining
	Low PCNA staining
	Low chromosomal aberrations

Figure 32.20 Spitz nevus composed of plump, spindle-shaped cells. (H&E)

Figure 32.21 Spitz nevus. Although this lesion is large, it shows symmetry. (H&E)

Figure 32.22 Spitz nevus. There is some upward spread of melanocytes within the epidermis, but most of the cells are in small nests and not single cells. (H&E)

on the basis of ultrastructural studies, that the process of ‘maturation’ of nevus cells is really one of atrophy.⁵⁰⁸ Confusion may be caused by a rare subset of malignant melanomas that show paradoxical maturation in depth.⁵⁰⁹ Single melanocytes extending upward within the epidermis are quite uncommon in Spitz nevi,^{274,510} although clusters of three or more cells may be found within the epidermis, in places appearing to be undergoing transepidermal elimination (Fig. 32.22). Prominent pagetoid spread of epithelioid melanocytes was reported in a series of small, uniformly pigmented macules, which often occurred on the lower legs of young female patients.⁵¹¹ The melanocytes were purely intraepidermal. There was a perception of ordered growth and minimal atypia. The term ‘*pagetoid Spitz nevus*’ has been used for these lesions, which show little, if any, junctional nesting (Fig. 32.23).^{512,513} Spitz nevi with *HRAS* alterations often are large with a sclerotic base.^{490,491}

Solitary or coalescent eosinophilic globules (Kamino bodies) may be found at the dermoepidermal junction.^{514,515} The presence of coalescent globules is an important diagnostic sign, but multiple step sections may be needed to demonstrate them (Fig. 32.24). They are usually PAS positive and trichrome positive.⁴⁴⁹ On immunohistochemistry, they contain various components of the basement membrane,

Figure 32.23 Pagetoid Spitz nevus. The cells are large and pagetoid, but there is no nesting or significant atypia. A Spitz nevus was present adjacent to this change. (H&E)

Figure 32.25 Spitz nevus. There is conspicuous 'cleavage' at the junctional zone resulting from the artifactual separation of nevus cells from the basal layer of the epidermis. (H&E)

Figure 32.24 Spitz nevus. (A) Coalescent eosinophilic globules ('Kamino bodies') are present in the junctional zone. (H&E) (B) They are well seen in the trichrome stain. (Masson trichrome)

including laminin and type IV and VII collagen,⁵¹⁶ but no keratin or S100 protein.⁵¹⁷ They are not an apoptotic product of keratinocytes or melanocytes.⁵¹⁸ Electron microscopy shows them to be composed of bundles of filaments situated extracellularly.^{514,515}

Minor diagnostic criteria include the presence of junctional cleavage (separation of the epidermis from nests of nevus cells at the junctional zone; **Fig. 32.25**), pseudoepitheliomatous hyperplasia,⁵¹⁹ an absence of epidermal consumption that is common in melanomas,⁵²⁰ superficial dermal edema and telangiectasia, giant nevus cells (both multinucleate and uninucleate), and an absence of nuclear pleomorphism.⁴⁴⁹ The multinucleate cells resembled Touton giant cells in one case.⁵²¹ Mitoses may be quite frequent in some actively growing lesions, but extreme caution should be adopted in making a diagnosis of Spitz nevus if mitoses, particularly atypical ones, are present in the deeper portion of a lesion. There may be an inflammatory infiltrate that shows perivascular localization.⁴⁵⁷ The infiltrate is more intense in the halo variant (see later). The vascularity of Spitz nevi is usually higher than that of melanomas, despite an earlier study that reached the opposite conclusion.^{522,523} The *angiomatoid* Spitz nevus has been regarded by some as a variant of desmoplastic nevus (see later). It can be a close simulator of regressing malignant melanoma.⁵²⁴ Not infrequently, individual nevus cells may be found at a depth of up to one high-power field or more below the deep aspect of the tumor. In some Spitz nevi of epithelioid cell type, a distinct component of smaller nevus cells is present, usually at the periphery of the lesion. The term 'combined nevus' has been used for this association of an intradermal nevus with a Spitz nevus, but it is also used for the combination of any two histological patterns of nevi, congenital or acquired, found in the same lesion.⁵²⁵⁻⁵²⁸ Other histological changes that occur, rarely, are stromal fibrosis, hyalinization of the stroma,⁵²⁹ and stromal mucin (*myxoid Spitz nevus*).⁵³⁰ The presence of tubules and microcystic structures may represent an artifact of fixation rather than a distinctive variant (*tubular Spitz nevus*), as originally thought.⁵³¹⁻⁵³³ *Rosette-like structures* constitute another histological variant.⁵³⁴

Harvell, Bastian, and LeBoit studied 22 cases of Spitz nevi that seemed to have been clinically removed but persisted and clinically recurred at the biopsy site.⁴⁴⁰ Although the majority of *recurrent lesions* exhibited asymmetry and pagetoid spread, the dermal component usually had a low mitotic rate and retained architectural and cytological maturation.⁴⁴⁰ A predominantly intraepidermal pattern resembling

that seen in recurrent 'common' nevi was often seen. A desmoplastic pattern was uncommon.⁴⁴⁰

The most common dermoscopic pattern in Spitz nevus is the starburst-like pattern, found in more than half of cases. This consists of pigmented striations and/or brown or black globules, distributed radially along the lesional margins.⁵³⁵ Approximately 22% of lesions show brown or gray central pigmentation with brownish globules along the margins, and 25% have an 'atypical' pattern with irregularly distributed structures and colors, foci of diffuse, irregular pigmentation, and whitish-blue veil.⁵³⁵ Angiomatoid Spitz nevus has shown an irregular pigmented network with a central lacunar white zone with short telangiectatic vessels.⁵³⁶

Distinction from malignant melanoma

The age of the patient has been used, with the help of Bayes' rule, to indicate the probability that a lesion is a Spitz nevus or a melanoma.⁵³⁷ The author of this paper concluded that 'routine histological findings trump all of the aforementioned probabilistic considerations'. Another study found that Spitz nevi predominate on the thighs in patients younger than 40 years of age, whereas melanomas predominate on the trunk in patients 40 years of age or older.⁵³⁸ Again, findings such as this are of no help in assessing a specific case.

In a histological review of Spitz nevi and melanomas in teenagers, McCarthy and colleagues found that features favoring malignancy were fine dusty cytoplasmic pigment, marginal or abnormal mitoses, epithelioid intraepidermal melanocytes below parakeratosis, dermal nests larger than junctional nests, and the mitotic rate in the papillary dermis.⁵³⁹ In a subsequent paper from the same unit, the authors highlighted the presence of good symmetry, Kamino bodies, and uniformity of cell nests or sheets from side-to-side as favoring Spitz nevus, and the presence of abnormal mitoses, a mitotic rate $>2/\text{mm}^2$, and mitotic figures within 0.25 mm of the deep border of the lesion as favoring a diagnosis of melanoma.⁵⁴⁰ Of course, if these criteria were used in making the initial diagnosis, they might be expected to be present in any subsequent review of the cases. In a similar study, Peters and Goellner found that pagetoid spread, cellular pleomorphism, nuclear hyperchromatism, and mitotic activity were greater in melanomas than in Spitz nevi.⁵⁴¹ These nuclear differences can be quantified using image analysis cytometry.⁵⁴² One study showed that multivariate DNA cytometry could be used with high accuracy to discriminate between Spitz nevi and malignant melanoma.⁵⁴³ Microfluorimetric analysis, computer-assisted image analysis, and flow cytometry have also been used.⁵⁴⁴⁻⁵⁴⁶ DNA *in situ* hybridization is another diagnostic tool with potential discriminatory value.⁵⁴⁷

Other techniques that may be applied in the diagnosis of Spitz nevi are immunohistochemistry⁵⁴⁸ and the measurement of nucleolar organizer regions (loops of DNA that transcribe ribosomal RNA and that are easily identified in paraffin-embedded sections using a silver stain).⁵⁴⁹ Unfortunately, neither method gives unequivocal results in borderline lesions (see later).⁵⁵⁰ With immunohistochemistry, the cells express NKI/C3, melan-A (MART-1), and S100 protein; the results are inconsistent with gp100 (HMB-45). This latter marker is usually expressed weakly in the superficial cells, but sometimes there is staining throughout the tumor in a pattern near to that seen in malignant melanoma.⁵⁴⁸ Nevertheless, even in these cases, it is often possible to discern less intense staining in the deeper cells than in the more superficial cells. This pattern, known as stratification, is not seen in melanomas.^{550,551} Stratification also occurs with cyclin D1, with positive cells in Spitz nevi being restricted to the upper dermis.⁵⁵² No stratification is seen with melan-A (MART-1), which stains some cells in a high proportion of Spitz nevi as well as melanomas.⁵⁵³ PCNA is expressed, usually weakly, in a variable number of nevus cells in a Spitz nevus; in melanomas, the expression of this antigen is usually stronger and more diffuse.^{554,555} Only 2 or 3% of cells express Ki-67, in contrast to malignant melanoma, in which approximately 15% or more of the cells are positive.^{552,556} p53 protein is detected in only occasional Spitz nevi by

immunohistochemistry.⁵⁵⁷ The expression of p27 is significantly higher in Spitz nevi than in melanomas.⁵⁵⁸ Activated Akt expression is increased in Spitz nevi and melanomas compared with benign intra-dermal nevi, but this seems to have little diagnostic use.⁵⁵⁹ The expression of CD117 is similar in Spitz nevus and malignant melanoma.⁵⁶⁰ The number of silver-positive nucleolar organizer regions (AgNOR score) is lower in Spitz nevi (mean, 1.2 per cell) than in malignant melanoma (mean, 2.0 per cell), but overlap occurs.^{549,561,562} Immunohistochemistry using S100 protein, melan-A (MART-1), and CD68 can be used to distinguish epithelioid Spitz nevi from epithelioid histiocytomas; the latter entity is positive for CD68.⁵⁶³ In one study, 56% of Spitzoid melanomas expressed CD99 compared with only 5% of Spitz nevi.⁵⁶⁴ Approximately one-half of the positive Spitzoid melanomas showed strong diffuse staining, a pattern not seen in Spitz nevi.⁵⁶⁴ A recent study using neuropilin-2 suggests positive staining is more indicative of Spitzoid melanoma than a Spitz nevus.⁵⁶⁵ Osteopontin is expressed in lower levels in Spitz nevi than in melanomas.⁵⁶⁶ C-fos protein expression does not distinguish Spitz nevi, common melanocytic nevi, and malignant melanomas.⁵⁶⁷

Comparative genomic hybridization (CGH) and fluorescence *in situ* hybridization (FISH) analysis of Spitz nevi show clear differences from melanoma, and both of these techniques are arguably the best currently available ancillary techniques for characterizing borderline lesions (see p. 890).^{490,568} Whereas melanomas show frequent chromosomal aberrations, the majority of Spitz nevi have a normal chromosomal complement or, occasionally, tetraploidy.^{490,569,570} Homozygous deletion of 9p21 (location of *CDKN2A/p16*) is particularly useful because it is commonly observed in Spitzoid melanomas but not Spitz nevi.⁵⁷¹ Although most studies have failed to demonstrate mutations in the *BRAF* gene in Spitz nevi, a minority have found these mutations similar to those in melanoma.^{492,572-574} Whereas *HRAS* mutations have been detected in approximately one-third of Spitz nevi, they have not been detected in Spitzoid melanomas.⁵⁷⁵ Activating hot spot mutations in the *BRAF*, *NRAS*, and *HRAS* genes were not identified in either Spitzoid melanomas or Spitz nevi in one report.⁵⁷⁶ In another study, both loss of heterozygosity and microsatellite instability failed to distinguish Spitz nevi from melanoma.^{577,578} Another technique that shows promise in the distinction of Spitz nevi and malignant melanoma is the measurement of telomerase activity, which is much lower in Spitz nevi than in malignant melanoma.⁵⁷⁹ However, more recent studies using the human telomerase RNA (hTER) component found no difference in expression, but the hTER levels do not necessarily correlate with the level of telomerase activity.^{580,581}

Although the misdiagnosis of malignant melanoma as a Spitz nevus is a well-recognized error, the reverse phenomenon – diagnosing a Spitz nevus as a melanoma – also occurs.⁵⁸² Even so-called 'experts' can occasionally disagree as to the correct diagnosis.⁵⁸³ Perhaps the time has come for us to acknowledge with honesty that some cases defy diagnosis using currently available criteria and ancillary tests.⁵⁸⁴⁻⁵⁸⁷ Unfortunately, the 'retrospectroscope' is not a freely available instrument. Elder and colleagues circumvent this problem by the use of the term 'MELTUMP' (melanocytic tumor of uncertain malignant potential) for these borderline lesions.⁵⁸⁸

Other considerations in differential diagnosis

Nesting of cells at the junctional zone and pigment production can allow the distinction of Spitz nevi from other lesions composed of epithelial or epithelioid cells, including squamous cell carcinomas and 'histiocytic' lesions such as xanthogranuloma, reticulohistiocytoma, and epithelioid cell histiocytoma. When the typical morphology of a melanocytic lesion is not present, differential immunostaining can be performed using melanocytic markers and other pertinent stains such as cytokeratin, CD68, and factor XIIIa (although some melanocytic lesions also express CD68). A dermal epithelioid Spitz nevus heavily infiltrated by T cells mimicked a granulomatous dermatitis; the correct

diagnosis was established by positive S100 staining of the cells and a molecular analysis showing an H27H mutation in the *HRAS* gene.⁵⁸⁹ There is a recent report of a clear cell sarcoma of the skin, with epidermal involvement, that initially was interpreted as a Spitz nevus. The diagnosis was established 12 years later when studies performed on metastatic tumor in an axillary lymph node revealed a t(12;22) translocation and FISH analysis showed the Ewing's sarcoma breakpoint region 1 (EWSR1) rearrangement in the majority of tumor cells.⁵⁹⁰

Atypical Spitz nevus (tumor)

'Atypical Spitz nevus' is the term used for a lesion in which a number of histological features deviate from the 'stylized depiction' of the Spitz nevus.^{377,500} The word 'tumor' has been suggested as more appropriate than 'nevus' in this context.^{591,592} 'STUMP' (Spitzoid tumors of uncertain malignant potential) has been used as an acronym for these lesions.⁵⁹³ The connotation of this diagnosis is that the malignant potential is uncertain, although untoward events have proved to be rare in retrospective series and in the pathologist's experience.⁵⁰⁰ It has been suggested that a diagnosis of 'probable Spitz nevus' is a more appropriate designation.⁵⁹⁴ Mones and Ackerman have criticized the concept of atypical Spitz nevus as being 'abject intellectually' because those who invoke the term never set forth in clear-cut fashion criteria for typical Spitz nevi, in contradistinction to atypical Spitz nevi.⁵⁹⁵ It seems likely that a histological continuum exists encompassing Spitz nevi at one end and Spitzoid melanoma at the other, with varying degrees of 'atypia' along this path.⁵⁸³ The degree of deviation from the 'norm' is sometimes semiquantified as mild/moderate/severe or low/intermediate/high.^{596,597} This latter scoring system has been used to indicate risk of metastasis (Spitzoid melanoma); it is an extension of the concept of atypical Spitz tumors.⁵⁹⁷ Factors contributing to a high risk of likely metastasis (i.e., the lesion was a melanoma and not a Spitz nevus) were age older than 10 years, diameter of the lesion greater than 10 mm, the presence of ulceration, involvement of the subcutis (Clark level V), and a mitotic rate of at least 6/mm².⁵⁹⁷ Spitzoid melanomas developing in teenagers do not have a better prognosis than that of other forms of melanoma.⁵⁹⁸ Some of the cases now reported as atypical Spitz nevi (tumors) have been reported in the past as minimal deviation melanoma of Spitz nevus-like type.⁵⁹⁹ Atypical Spitz nevus is not the same as dysplastic Spitz nevus, a recently recognized variant of dysplastic nevus. The term 'spitzoid Clark's nevus' has also been used when there are cytological features of a Spitz nevus and architectural features of a Clark's nevus.⁶⁰⁰

Sentinel lymph node biopsy has been advocated by some to characterize atypical Spitzoid lesions.^{499,601} Urso *et al.* found nodal metastases in 4/12 patients who had lesions categorized as 'atypical Spitz tumors',^{602,603} but Wick and others have questioned the significance of this finding in the absence of studies on the frequency of ectopic melanocytic cell groups in patients with ordinary Spitz nevi.^{604,605} LeBoit has also criticized the routine use of sentinel lymph node biopsy for ambiguous lesions.^{606,607} Busam and Pulitzer have also cautioned against performing the procedure as a diagnostic adjunct, as have others.^{608,609}

Mooi and Krausz concluded their critique of the paper by Mones and Ackerman⁵⁹⁵ by advocating the use of three diagnostic categories: Spitz nevus, Spitzoid melanoma, and a provisional group called 'Spitz tumor of uncertain malignant potential'.⁶¹⁰ Barnhill also favors three categories of lesions, but he discourages the use of the term 'Spitzoid melanoma', which is often used indiscriminately for tumors of uncertain biological nature.⁶¹¹ CGH and FISH analyses will be of great value in the future for characterizing these borderline lesions (see p. 890).

Halo Spitz nevus

The term 'halo Spitz nevus' is used here for nevi with a depigmented rim, corresponding to that seen in the usual halo nevus, and for nevi

with a heavy lymphocytic response resembling that seen in halo nevus but with sparing of adjacent basal melanocytes.^{461,612,613} This latter group, which does not develop a depigmented halo clinically, may also be designated *nevus with halo reaction*.⁶¹² This phenomenon represents an early stage of nevus involution. It is often seen in combined nevi in which one component is an epithelioid Spitz nevus and the other a more traditional nevocellular nevus.⁶¹³

The inflammatory response may induce reactive cytological atypia. Mitoses, if present, are superficial in location.

Desmoplastic nevus

Desmoplastic nevus, which may be mistaken clinically for a fibrohistiocytic lesion such as a dermatofibroma or epithelioid histiocytoma,^{614,615} is probably a variant of Spitz nevus with stromal desmoplasia, although desmoplastic variants of common melanocytic nevi probably develop. MacKie and Doherty believe that it is a discrete entity.⁶¹⁶ This opinion is shared by Sherrill *et al.*, who believe it is a unique form of benign melanocytic nevus distinct from conventional compound nevus, epithelioid blue nevus, and desmoplastic melanoma as well as Spitz nevus.⁶¹⁷

A variant of giant congenital nevus has been named **desmoplastic hairless hypopigmented nevus** by Ruiz-Maldonado *et al.*⁶¹⁸ It shows progressive hardening and depigmentation throughout the years.⁶¹⁹ In one recent case, a proliferative nodule developed in such a lesion; indolent biologic behavior was found, despite FISH results compatible with melanoma.⁶²⁰

Angiomatoid Spitz nevus is a distinct variant of desmoplastic nevus with prominent vasculature and some plump endothelial cells.^{524,621} A variant with deep vascular proliferation has been reported.⁶²²

Histopathology

The desmoplastic nevus is characterized by a sclerotic dermis, sparse pigmentation, and little or no junctional activity and nest formation.⁶¹⁴ Well-defined intranuclear invaginations of cytoplasm are present in most cases. The cells express S100 protein.⁶¹⁶ Superficial dermal cells may also express HMB-45.⁶¹⁵

A related variant is the *hyalinizing Spitz nevus*, in which there is extensive stromal hyalinization.⁵²⁹

Plexiform Spitz nevus

The exceedingly rare plexiform variant of Spitz nevus has no distinguishing clinical features. It is characterized by a plexiform arrangement of bundles and lobules of enlarged spindle to epithelioid melanocytes throughout the dermis.⁶²³ Some lobules are surrounded by a thin rim of compressed stroma. A myxoid stroma was present in the two cases initially reported.⁶²³

Malignant Spitz tumor

The term 'malignant Spitz tumor' has been used for a very rare lesion with a close histological resemblance to a Spitz nevus but larger (with a diameter >1 cm) and which extends into the subcutaneous fat.⁵⁰⁰ It may metastasize to regional lymph nodes but not beyond.^{449,624,625} More than 100 cases of metastasizing Spitz tumors have been reported since 1948, but this term encompasses several different concepts.⁶²⁶ Barnhill's review of his cases of childhood melanomas gives some support to the notion that there is a Spitz-like tumor in childhood that may metastasize to regional nodes without further aggressive disease.⁶²⁷ The diagnosis should not be used for all diagnostically difficult tumors or for melanomas that have been misdiagnosed as Spitz nevi and that are reviewed after metastases have developed. The three cases described by LeBoit as melanomas arising within a pre-existent Spitz nevus are also different lesions.⁶²⁸ Retrospective CGH or FISH analysis of these lesions may shed light on their true biology.

Histopathology

The malignant Spitz tumor is characterized by a relatively high mitotic rate and mitoses deep within the lesion. There is more cellular pleomorphism, less maturation in depth, and less cohesion of cells than in the usual Spitz nevus. In the few cases examined by immunohistochemistry, the cells contained S100 protein.⁶²⁴ HMB-45 was expressed either focally or diffusely.

PIGMENTED SPINDLE CELL NEVUS

Pigmented spindle cell nevus (Reed nevus) is now regarded as a distinct entity and not as a variant of the spindle cell type of Spitz nevus,^{629–631} although the distinction between a Reed nevus and a pigmented Spitz nevus is not always easy.⁶³² It is an uncommon lesion with a distinctive clinical presentation: a well-circumscribed deeply pigmented papule, usually of recent onset, frequently located on the thighs of young adults.⁶²⁹ A hypopigmented variant has been described.⁶³³ Pigmented spindle cell nevus is more common in females. Clinical follow-up has not so far suggested any aggressive behavior.⁶²⁹

Histopathology

The histological appearances are sometimes quite worrisome because of the presence of some pagetoid spread of cells and also some cytological atypia.^{274,634,635} The tumor is composed of spindle-shaped cells in nests, with the formation of interconnected fascicles (Fig. 32.26).⁶³⁰ Dendritic melanocytes, outside the junctional nests, are present in approximately 40% of cases.⁶³⁶ It is usually heavily pigmented, and many melanophages may also be present. A variant with excessive melanophages resembling tumoral melanosis has been described.⁶³⁷ Eosinophilic globules (Kamino bodies), resembling those seen in a Spitz nevus (discussed previously), can be demonstrated in most cases if 'step sections' are examined.⁶³⁸ They are present in approximately half the cases if only one section is examined.⁶³⁹ They sometimes contain melanin granules. Junctional clefting, similar to that seen in the Spitz nevus, is often present.⁶³⁹ Features distinguishing the pigmented spindle cell nevus from malignant melanoma include a symmetrical and orderly growth pattern, maturation of nevus cells in the deeper aspects of the lesion, and limitation of any pagetoid spread of melanocytes to the lower half of the epidermis.⁶³⁴

Pigmented spindle cell nevi only rarely have chromosomal abnormalities as determined by FISH analysis, which may be useful for distinguishing these nevi from melanoma in ambiguous cases.⁶⁴⁰

A pigmented epithelioid cell nevus also occurs; this is best regarded as a variant of Spitz nevus.^{641,642}

Pigmented spindle cell nevi have a distinctive dermoscopic appearance,⁶⁴³ with three common patterns: a starburst pigmentation pattern (seen in more than half of cases), a pattern of pigment globules at the edges of a central pigmented zone (seen in ~22% cases), and an atypical pattern that features asymmetry, diffuse irregular pigmentation, and a whitish-blue veil.⁶⁴⁴

Differential diagnosis

In a detailed comparison of pigmented spindle cell nevus and spindle cell melanoma, Diaz *et al.* found that symmetry, relatively sharp lateral demarcation, and uniformity of melanocytic nests were features favoring the former; pagetoid spread and adnexal involvement were encountered in both tumors.⁶⁴⁰ Immunohistochemical differences could be found in the expression of Ki-67 (0–5% in pigmented spindle cell nevi and 12.7% in spindle cell melanomas); cyclin D1 (12.4% in nevi and 41.5% in melanomas); and survivin, a member of the apoptosis inhibitor family, which is negative in nevi and positive (although to a low degree) in melanomas.⁶⁴⁰ FISH results were also helpful in that only 1 (of 15) pigmented spindle nevus showed a 'positive' result (abnormal number of copies of *RREB1* but a normal relation with

Figure 32.26 Pigmented spindle cell nevus. (A) The fascicles of spindle-shaped cells are confined, as is usual with this lesion, to the epidermis and the papillary dermis. There is some melanin incontinence at the base of the lesion. (B) The cells are nested. (H&E)

CEP6), whereas 11 (of 15) cases of spindle cell melanoma produced positive results.⁶⁴⁰

CONGENITAL NEVUS

Congenital nevi are found in approximately 1% of newborn infants.^{645–647} They are usually solitary,⁶⁴⁸ with a predilection for the trunk, although other sites such as the lower extremities and the scalp may also be involved.⁴⁴⁹ In one series, 29% of congenital nevi were 1–9 mm in diameter, 63% were 10–40 mm, and the remainder were larger.⁶⁴⁸ The majority of nevi that appear subsequent to birth are less than 10 mm in diameter. Some children develop early onset nevi, usually small and visible by the age of 2 years, with both the clinical and the histological characteristics of congenital nevi. They are often referred to as congenital nevus-like nevi. They may be considerably more common than true congenital nevi, and they may affect 6–20% of adolescents and adults.⁶⁴⁹ The term 'nevus tardive' has also been used for this group.⁶⁵⁰ Giant congenital nevi (i.e., those measuring >20 cm in greatest diameter) often have a garment (e.g., a bathing trunk) distribution.^{651,652} Medium-sized lesions measure 1.5 cm up to 19.9 cm in diameter, whereas small lesions are less than 1.5 cm in diameter.

Attempts have been made to stratify further the measurement of congenital nevi in the hope that this reveals more information on the comparative risk of developing melanoma.⁶⁵³ Giant nevi may be associated with leptomeningeal melanocytosis (neurocutaneous melanosis).⁶⁵⁴⁻⁶⁶⁰ The receptor for hepatocyte growth factor/scatter factor (HGF/SF), a multifunctional cytokine, has been detected in a congenital nevus in a patient with neurocutaneous melanosis. Transgenic mice overexpressing this factor develop similar lesions, supporting the pathogenetic role of this proto-oncogene in neurocutaneous melanosis.⁶⁶¹

A review of 1008 patients with large or multiple congenital melanocytic nevi found that 4.8% of patients with truncal nevi developed symptomatic neurocutaneous melanocytosis (NCM), and one-third of these patients died.⁶⁶² Of those with head or extremity large nevi, only 0.8% developed symptomatic NCM, and none had died according to a report published in 2006.⁶⁶² Of the small number of patients ($n = 17$) with multiple congenital melanocytic nevi⁶⁶³ but without a giant nevus, 71% developed symptomatic NCM, and 41% died of it.⁶⁶² Asymptomatic NCM (determined by MRI) was present in only 4.8% of patients in one study of patients with large congenital nevi – a much lower figure than previously obtained.⁶⁶⁴ Some workers in this field believe that patients with multiple congenital melanocytic nevi form a unique group in the spectrum of congenital melanocytic nevi.⁶⁶⁵ If these nevi form satellites around a large congenital nevus, there is a high risk of NCM.⁶⁶⁶⁻⁶⁶⁸ Parenthetically, NCM has been associated with the Dandy-Walker syndrome.^{669,670} It may also be associated with mass lesions in the brain,⁶⁷¹ leptomeningeal melanoma,⁶⁷² encephalocranio-cutaneous lipomatosis,⁶⁷³ and transposition of the great arteries and renal agenesis.⁶⁷⁴ A recent paper reported the association of congenital nevus and neurocutaneous melanoma with the tuberous sclerosis complex.⁶⁷⁵ Peritoneal metastases have been reported in 2 patients who had earlier received a ventriculoperitoneal shunt for hydrocephaly produced by NCM.⁶⁷⁶

Studies have been undertaken to ascertain whether the size of congenital nevi remains static during overall body growth. In infants younger than 6 months of age, more than half of the small congenital nevi followed in one study enlarged disproportionately to the growth of the anatomical region, whereas beyond 6 months of age such growth was very uncommon.⁶⁷⁷ Spontaneous involution has been recorded, but this seems to be an uncommon event.⁶⁷⁸ Erosions and ulcerations are sometimes noted in giant congenital nevi in the neonatal period.⁶⁷⁹ Such changes are not necessarily an indication of malignancy.⁶⁸⁰ In adults, congenital nevi remain static in appearance in the absence of malignancy, trauma, infection, or stretching of the skin.⁶⁷⁷

Congenital nevi can be associated with several syndromes, including Carney's syndrome (including LAMB and NAME syndromes; see p. 838), the epidermal nevus syndrome, neurocutaneous melanosis (discussed previously), neurofibromatosis type I, the premature aging syndrome, and occult spinal dysraphism.⁶⁸¹⁻⁶⁸³ A retroperitoneal malignant schwannoma has been reported in an infant with a giant congenital nevus.⁶⁸⁴ This may represent a further 'syndrome', previously unreported. A benign schwannoma has also occurred.⁶⁸⁵ Other clinical presentations include a halo variant,⁶⁸⁶⁻⁶⁸⁹ an eczematous halo (the Meyerson phenomenon),⁶⁹⁰ an exceedingly rare linear form,⁶⁹¹ and an equally rare segmental agminate form.^{692,693} The halo phenomenon may be associated with leukoderma within the nevus and/or vitiligo-like depigmentation elsewhere on the body.^{694,695} A progressive sclerodermoid reaction has also been reported in a giant congenital nevus.⁶⁹⁶⁻⁶⁹⁸ It may be associated with progressive depigmentation.^{618,699} Intractable pruritus leading to life-threatening blood loss is another rare presentation.⁷⁰⁰

There is a significant risk of melanoma, both cutaneous and extracutaneous, developing in a giant congenital nevus.^{701,702} This risk has been placed at between 2 and 31%, although a figure of approximately 5% or less seems more realistic.⁴⁴⁹ A more recent paper, based on a

prospective study of 46 patients, reported a cumulative 5-year risk of melanoma of 5.7%.⁷⁰³ Axial lesions appear to be more at risk for developing melanomas than lesions on the extremities.⁷⁰⁴ The risk of melanoma development in a Southeast Asian cohort of patients with large congenital melanocytic nevi appears to be very low.⁷⁰⁵ The risk with small and medium-sized congenital nevi is more controversial.^{701,706-709} Some have claimed that it is quite small^{651,701,709-711} or non-existent,^{712,713} whereas others have estimated the cumulative risk as 3–20 times the usual risk.⁷¹⁴ Evidence of a pre-existing congenital nevus has been found in 1.1%⁶⁵¹ and 8.1%⁷¹⁵ of melanomas in two studies. One of the problems in assessing this risk is that the histological features of congenital nevi are not always distinguishable from those of acquired nevi. Accordingly, Rhodes and colleagues⁷¹⁶ have subsequently cautioned that their earlier work suggesting the presence of a pre-existing congenital nevus in 8.1% of melanomas⁷¹⁵ may be giving a falsely high figure. Another study found that 44% of melanomas developing in patients younger than 30 years of age developed in a small nevus present either from birth or from early childhood. This study suggests that small early onset nevi may have a higher potential for postpubertal malignant change than has been previously recognized.⁷¹⁷ A systematic review published in 2006 and incorporating 6571 patients found that the overall risk of melanoma in all 14 studies included was 0.7%.⁷¹⁸ The melanoma risk strongly depends on the size of the nevus and is highest in those nevi traditionally designated as garment nevi.⁷¹⁸ The median age at diagnosis of the melanoma was only 7 years.⁷¹⁸ Patients with multiple congenital melanocytic nevi are at risk for developing melanoma. In one study, 6.7% developed cutaneous melanomas.⁷¹⁹ Melanoma change had not been reported in lesions treated with laser therapy^{720,721} until comparatively recently.⁷²²

A study of G₁ cell cycle regulators in congenital melanocytic nevi has found no similarities with malignant melanoma, indicating that the relationship between these two entities is not, as yet, transparent.⁷²³ *BRAF* mutations have been reported in small- and medium-sized congenital nevi, although they may not be present in lesions that were actually present at birth.⁷²⁴ *NRAS* mutations are present at high frequency in giant congenital nevi.^{725,726}

A **congenital melanoma** arising in a giant congenital nevus is an exceedingly rare event.⁷²⁷ It has also been recorded in the absence of an underlying congenital nevus.⁷²⁸ Prenatal metastases have also been recorded,⁷²⁷ although many of the reported cases have done well, with no evidence of metastasis.⁷²⁹ Nevus cells may be found in the placenta in association with giant congenital pigmented nevi. They should not be overdiagnosed as indicating malignancy.⁷²⁹⁻⁷³¹

A rare form of congenital nevus is the divided (kissing) nevus that occurs on adjacent parts, such as the upper and lower eyelids, and may appear as one lesion when the eyelids are closed. A divided nevus has also been reported on the penis.^{732,733}

Treatment of congenital nevi

Most authorities agree that giant congenital melanocytic nevi should be removed whenever possible because they are disfiguring and potentially malignant.⁷³⁴⁻⁷³⁶ Because most are too large to be removed by traditional surgery, various debulking procedures are usually applied. Curettage in the neonatal period has been successful, as indicated by a recent series of cases extending over a 20-year period.⁷³⁷ Rapid, severe repigmentation has been reported following curettage and dermabrasion of large congenital nevi.⁷³⁸ Because there are distinct phenotypic changes between the superficial and the deep component of giant congenital melanocytic nevus, this has been used as a rationale for curette.⁷³⁹ Digital dermoscopy can be used in this follow-up.⁷⁴⁰ It can also be used to monitor congenital nevi that have not undergone treatment.^{741,742} The dermoscopic pattern of congenital nevi varies with the age of the patient and the lesional site.⁷⁴³ Positron emission tomography can also be used to monitor giant nevi for the development of melanoma.⁷⁴⁴ Melanoma has developed in a giant nevus 40 years after

its partial surgical removal.⁷⁴⁵ Removal of these large lesions is not recommended in patients with symptomatic neurocutaneous melanocytosis because the prognosis is poor.⁷⁴⁶

Erbium:YAG laser resurfacing is an effective method of ablating medium and large congenital nevi.⁷⁴⁷ Staged excision with grafting, Q-switched ruby laser, and close observation have also been used. For medium-sized congenital nevi, excision during the pubertal years is the practice of some specialized clinics,⁶⁵⁰ whereas for small lesions with a regular outline, lifelong observation by the patient is usually carried out.⁶⁵⁰

Histopathology

Congenital nevi may be junctional, compound or intradermal in type, depending on the age at which they are removed. In neonates, they are often junctional,⁷⁴⁸ and if biopsied in the first week of life, the melanocytic hyperplasia may be quite prominent in the epidermis and adnexal epithelium.⁷⁴⁹ Two types of cells have been reported in congenital nevi removed in the first year of life. There are small nevus cells in the reticular dermis, usually separated by a space from overlying larger cells in the epidermis or close under it.⁷⁵⁰ Features that have traditionally been regarded as characteristic of congenital nevi removed after the neonatal period are the presence of nevus cells in the lower two-thirds of the dermis; extension of nevus cells between collagen bundles singly or in Indian file; and extension of cells around nerves, vessels, and adnexae (Fig. 32.27).⁷⁵¹⁻⁷⁵³ Although one study showed extension of nevus cells into the deep dermis in only 37% of congenital nevi,⁷⁵⁴ a more recent immunohistological investigation using S100 protein staining found nevus cell involvement of adnexae in all cases.⁷⁵⁵ Another study found a poor correlation between the histology and the clinical history of the lesion – congenital or acquired.⁷⁵⁶ Involvement of eccrine glands and septa are said to be the most specific features of a true congenital nevus.⁷⁵⁶ Full-thickness dermal involvement, which is clearly visible in routine H&E-stained sections, seems to be a feature of the larger congenital nevi but not the smaller ones,⁷⁵⁷ which may have a patchy distribution of nevus cells in the dermis.⁵¹¹ According to some, small congenital nevi do not differ appreciably from acquired nevi.^{758,759} The contrary view is that use of the traditional histological criteria (discussed previously) makes it possible to differentiate the majority of small congenital melanocytic nevi from acquired melanocytic nevi.⁷⁶⁰ Underlying hypoplasia of the subcutaneous fat and loss of elastic tissue from the papillary dermis producing anetoderma-like changes have both been reported in congenital nevi.^{761,762} Lipomatosis

has been associated with a giant nevus.⁷⁶³ Cartilaginous differentiation has also been reported.⁷⁶⁴ Ki-67 has a limited expression in 1 or 2% of the nuclei, mainly in the junctional and upper dermal components.⁷⁶⁵ Bcl-2 shows strong cytoplasmic expression in greater than 70% of the nevus cells.⁷⁶⁵

The melanomas that develop in small congenital nevi have been said to have less aggressive growth than other melanomas,⁷¹⁵ but this remains to be confirmed. In giant congenital nevi, the melanomas are often nonepidermal in origin.⁷⁶⁶ Their metastatic potential is well recognized.⁷⁶⁷ Patterns described include spindle and round cell differentiation; malignant blue nevus; and heterologous malignant mesenchymal differentiation, including neurosarcoma,⁷⁶⁸ rhabdomyosarcoma,^{769,770} liposarcoma, and undifferentiated spindle cell carcinoma.⁷⁷¹

Sometimes, a cellular (proliferative) ‘nodule’ of large epithelioid cells is present at birth or develops in a congenital nevus;⁷⁷²⁻⁷⁷⁵ it should not be misdiagnosed as a melanoma. It is usually less than 5 mm in diameter.⁷⁷⁶ Extensive proliferative nodules sometimes develop.⁷⁷⁷ The proliferative nodule may have features of a deep penetrating nevus,⁷⁷⁸ a balloon cell nevus,⁷⁷⁹ or a Spitz nevus.⁷⁸⁰ Features that favor a diagnosis of malignancy include the presence of atypical mitoses or focal necrosis within the ‘nodule’ or a lack of circumscription, with nests of cells infiltrating into the adjacent nevus. The ‘melanoma simulant cells’, as they have been called,⁷⁸¹ often blend imperceptibly with the more banal nevus cells surrounding the nodule.^{729,782,783} Rosette formation has been described in a cellular nodule.⁷⁸⁴ Similar cellular nodules may develop in acquired nevi (‘clonal nevi’), although they do not usually have the nuclear variability seen in the cellular nodules of congenital nevi. An immunohistochemical study of proliferative (cellular) nodules and congenital nevi away from the nodules found similar expression of melanocytic, lymphocytic, and most cell cycle/proliferative and apoptotic markers, including MIB-1, p16, p21, p27, c-myc, CD95, and bcl-2.⁷⁸⁵ However, c-kit (CD117) was expressed in nearly all proliferative nodules but not in the adjacent congenital nevus.⁷⁸⁵ Atypical features, resembling those seen in dysplastic nevi, are occasionally seen in congenital nevi.⁷⁸⁶ Comparative genomic hybridization has been used to confirm the benign nature of these proliferative nodules.⁷⁷⁸

There is a significant association between the presence of nevus cells in lymph nodes (nodal nevi) and cutaneous nevi in corresponding catchment areas of the skin. The link with cutaneous nevi of congenital type is even stronger.^{787,788} These nodal nevus cells express S100 protein and melan-A but not HMB-45 or Ki-67.⁷⁸⁹

Figure 32.27 Congenital nevus. Nests of nevus cells extend deeply in the dermis. (H&E)

DERMAL MELANOCYTIC LESIONS

Dendritic melanocytes are present in the dermis.⁷⁹⁰ These melanocytes may be derived from precursor cells that did not complete their migration from the neural crest to the epidermis during embryogenesis. This theory has been confirmed by a study of melanoblasts using microphthalmia transcription factor in embryos.⁷⁹¹ The dermal melanocytoses have been reviewed by Asher and Calonje.⁷⁹² Zembowicz and Mihm also reviewed this topic in 2004.⁷⁹³

MONGOLIAN SPOT

Mongolian spots are slate-colored patches of discoloration with a predilection for the sacral region of certain ethnic groups, particularly Chinese and Japanese people.⁷⁹⁴ They are present at birth or soon afterwards, but they tend to disappear with increasing age, except in the Japanese, among whom persistent lesions may be found in approximately 3% of middle-aged adults.⁷⁹⁵ Persistent Mongolian spots have been reported rarely in Chinese adults.⁷⁹⁶ Rare clinical variants include the presence of a depigmented halo;⁷⁹⁷ the development of a darker

pigmented Mongolian spot superimposed on another Mongolian spot;⁷⁹⁸ adult onset;⁷⁹⁹ and occurrence on the scalp, temple, and in cleft lips.^{800–802} Mongolian spots have been reported in patients with mucopolysaccharidoses,^{803,804} particularly Hunter syndrome,⁸⁰⁵ and in one child with Sjögren–Larsson syndrome.⁸⁰⁶ The pigmentation associated with minocycline therapy may rarely simulate a Mongolian spot.⁸⁰⁷

Histopathology

There are widely scattered, melanin-containing melanocytes in the lower half of the dermis. The cells are elongated and slender. Occasional melanophages are also present.

NEVUS OF OTA AND NEVUS OF ITO

The nevus of Ota is a diffuse, although sometimes slightly speckled, macular area of blue to dark brown pigmentation of skin in the region of the ophthalmic and maxillary divisions of the trigeminal nerve.^{808,809} There is often conjunctival involvement as well. Ipsilateral deafness is a rare event.⁸¹⁰ Lesions are bilateral in a small number of cases.^{811–813} There is a predilection for certain races and for females. It affects approximately 0.02% of the Asian population and nearly 0.2% of Japanese people.⁸¹⁴ It is uncommon in white populations. The nevus of Ito is a similar condition located in the supraclavicular and deltoid regions and sometimes in the scapular area.⁸¹⁵ Both lesions are occasionally present in the same patient.⁸¹¹ Bilateral nevus of Ito has been reported in association with nevus spilus.⁸¹⁶ Pigmentation is often present at birth, but it may not become apparent until early childhood or puberty. A late-onset Ito's nevus that developed in a 70-year-old white woman has been reported.⁸¹⁷ Such a lesion is a site-specific variant of acquired dermal melanocytosis.⁸¹⁷ The halo phenomenon is a rare cause of depigmentation in one of these lesions.⁸¹⁸ Malignant change is exceptionally rare.^{819,820} There is one report of a nevus of Ota that locally invaded bone and dura over a period of 50 years. It was histologically benign in appearance.⁸²¹

A recent case of nevus of Ota evolved to melanoma with intermediate stages resembling cellular blue nevus.⁸²² Comparative genomic hybridization showed gains in the distal arm of chromosomes 1q and 6p, the distal arms of 9q and 8q, and loss of 6q in melanoma areas and not in blue nevus areas.⁸²² FISH studies showed gains in 6p25 and losses in 6q23. Copy numbers of 6p25 varied within malignant areas, with the highest number of signals in expansile nodular areas; FISH analysis did not detect chromosomal abnormalities in blue nevus areas.⁸²² Another study showed *BRAF* mutations in meningeal melanocytomas associated with nevus of Ota.⁸²³ Two acquired dermal melanocytoses that appear in adult life, often in the distribution of the nevus of Ota, have been described. **Hori nevus** refers to bilateral nevus of Ota-like macules usually on the malar regions, whereas **Sun nevus** is acquired unilateral nevus of Ota.^{817,824} Aggravating factors for Hori's nevus include sun exposure and pregnancy.⁸²⁵ Because the lesions become progressively more confluent and gray over time, it has been suggested that melanocytes migrate from the epidermis to the deeper dermis over this period.⁸²⁵ Nevus of Hori has also developed after aggravated atopic dermatitis.⁸²⁶

Surgical excision is one method of treatment.⁸²⁷ Laser therapy has also been used to treat these lesions.⁸²⁸ Nevus of Ota and related lesions have been successfully treated by fractional photothermolysis using a fractionated 1440nm Nd:YAG laser.⁸¹⁴ Dermabrasion and cryotherapy are other modes of treatment.

Histopathology

There are often nodular collections of melanocytes that resemble those of blue nevi (see later). The intervening macular areas are composed of a more diffuse infiltrate of elongated melanocytes situated in the upper dermis.⁸²⁹ In Hori's nevus, the melanocytes are located in the

middle and upper dermis, and on electron microscopy melanosomes are in stages II–IV of melanization.⁸²⁵

Differential diagnosis of dermal melanocytoses

In lesions with few dermal melanocytes that are widely distributed and only lightly pigmented, it may be difficult to make a diagnosis of dermal melanocytosis in the absence of an index of suspicion or clinical guidance. This is particularly the case for Mongolian spots. Therefore, dermal melanocytosis should be included as one of the 'invisible dermatoses'. Blue nevus differs by having more concentrated aggregates of pigmented dendritic melanocytes, although the occasional nodular foci within nevus of Ota or nevus of Ito can be virtually indistinguishable from blue nevi.

BLUE NEVUS

The common or classic blue nevus is a small slate-blue to blue-black macule or papule found most commonly on the extremities. Subungual lesions are rare.^{830–832} It is almost invariably acquired after infancy,⁸³³ but a giant congenital lesion has been reported.⁸³⁴ The cellular variant is a much larger nodular lesion, often found on the buttocks but sometimes on the scalp⁸³⁵ or the extremities.^{836–839} The eyelid is a rare site.⁸⁴⁰ Eruptive,^{841–843} plaque,^{844–847} target,⁸⁴⁸ amelanotic,⁸⁴⁹ linear,⁸⁵⁰ satellite,⁸⁵¹ disseminated,^{852–854} and familial^{855,856} forms have been described. Eruptive multiple blue nevi have developed on the penis in a young adult.⁸⁵⁷ The term 'agminate blue nevus' has sometimes been used for the eruptive and plaque variants.^{858,859} The infiltrating giant cellular blue nevus may involve half the face and extend into striated muscle and the maxillary sinus.⁸⁶⁰

The epithelioid blue nevus is a variant that clinically resembles the common blue nevus, except for its distinct histological appearance, its tendency to be multiple, and its association with the Carney complex (see p. 417).^{861–863} A variant of epithelioid blue nevus presenting as a giant congenital nevus has been reported.⁸⁶⁴ However, epithelioid blue nevus is not always associated with the Carney complex.^{865–867} None of the four cases of epithelioid blue nevus of the genital mucosa was associated with the Carney complex.⁸⁶⁸ Some authors have sought to combine epithelioid blue nevus with animal-type melanoma under the rubric 'pigmented epithelioid melanocytoma' – a controversial term that is discussed further later (p. 898).

Recently, *GNAQ* and *GNA11* mutations have been identified in the majority (up to 80%) of blue nevi.^{869,870}

The various types of blue nevi can often be identified by dermoscopy, based on their unique color variations.^{871,872}

Histopathology

The *common blue nevus* is composed of elongated, sometimes finely branching, melanocytes in the interstices of the dermal collagen of the mid and upper dermis (Fig. 32.28). There are some melanophages. Some lesions show dermal fibrosis (sclerosing blue nevus). A sclerosing 'mucinous' blue nevus with both stromal sclerosis and abundant mucin has been described.⁸⁷³ In approximately 3% of cases, there is minimal pigment present. Such cases have been called 'amelanotic' or 'hypopigmented' blue nevi.^{874–876} Occasionally, an overlying intradermal nevus is present: such lesions are called combined^{875,877,878} or 'true and blue' nevi. *Combined nevi* are characterized by the presence of two or more different types of melanocytic nevi in a single lesion.⁸⁷⁹ 'True and blue' nevi are the most common type of combined nevus.⁸⁷⁹ A rare finding is an overlying lentigo or junctional lentiginous nevus,^{880–884} a junctional Spitz nevus,⁸⁸⁵ or a dendritic component.⁸⁸⁶ This latter lesion, which combines a proliferation of junctional dendritic melanocytes arranged individually along the dermoepidermal junction with a common blue nevus in the dermis, has been called a '*compound blue nevus*'.^{792,887,888} A *persistent (recurrent) blue nevus* has also been

Figure 32.28 Blue nevus. Melanocytes with long dendritic processes and cytoplasmic melanin are present between the collagen bundles in the dermis. (H&E)

described.⁸⁸⁹ It may extend significantly beyond the scar of the original excision, which may lead to a clinical misdiagnosis of melanoma.⁸⁸⁹ Melanoma *in situ* has also developed over a combined blue nevus.⁸⁹⁰

The *cellular blue nevus* is composed of dendritic melanocytes, as in the common type, together with islands of epithelioid and plump spindle cells with abundant pale cytoplasm and usually little pigment (Fig. 32.29).⁸⁹¹ Congenital pauci-melanotic cellular blue nevi have been described.⁸⁹² Acquired amelanotic cellular blue nevi also occur.⁸⁴⁹ Heavily pigmented variants do occur. Melanophages are found between the cellular islands. The tumor often bulges into the subcutaneous fat as a nodular downgrowth that has a rather characteristic appearance. There are solitary reports of a lesion with subcutaneous cellular nodules⁸⁴⁵ and one of bony infiltration by a scalp lesion.⁸⁹³ Nerve hypertrophy is often present with perineural aggregation of cells.⁸⁹⁴ The giant cellular blue nevus of the scalp can be mistaken for a melanoma. Stromal desmoplasia (desmoplastic cellular blue nevus) and balloon cell change are rare occurrences.^{895,896} A brisk lymphocytic host response is a rare finding.⁸⁴⁹

The *epithelioid blue nevus* is composed of intensely pigmented globular and fusiform cells admixed with lightly pigmented polygonal and spindle cells. It shows symmetry on low power. It is a dermal

Figure 32.29 Cellular blue nevus. (A) The lesion fills the dermis and bulges into the subcutaneous fat. (B) There are nests and fascicles of melanocytes, some with a spindle shape. The cytoplasm of the cells is pale staining. (H&E)

lesion that, like the cellular blue nevus, may show extension into the subcutis.⁷⁹² The melanocytes are usually dispersed as single cells among the collagen bundles, although occasional fascicles exist. This pattern distinguishes this entity from the deep penetrating nevus, although some cases of epithelioid blue nevus resemble what has been called the superficial variant of deep penetrating nevus. There is usually no maturation in depth, a feature common to all blue nevi.⁷⁹² The epithelioid blue nevus is often part of a combined nevus that may include Spitz nevus, desmoplastic nevus, or congenital nevus. The combination of epithelioid blue and Spitz features in the one lesion has been called a **blitz nevus**.^{897,898} Some consolidation of the nomenclature is clearly needed in this area.

Rare variants include the association of a blue nevus with osteoma cutis,⁸⁹⁹ and with a trichoepithelioma,⁹⁰⁰ and a bizarre blue nevus with striking cytological atypia but without any other features of malignancy.⁹⁰¹ Perifollicular pigment-laden spindle cells, similar to those seen in a pilar neurocristic hamartoma, are rarely present.⁹⁰² Sebocyte-like melanocytes were present in one desmoplastic blue nevus.⁹⁰³ Central myxoid change (myxoid blue nevus) is another rare histological finding.⁹⁰⁴ The angiomatoid cellular blue nevus has a conspicuous vascular component resembling hemangioma.⁹⁰⁵ Another variant of blue nevus is the 'ancient' blue nevus, a variant of cellular blue nevus with degenerative stromal changes.⁹⁰⁶ In addition to pleomorphic and

multinucleate melanocytes, there were striking pseudoangiomatous features, hyaline angiopathy, and myxoid change.⁹⁰⁶

The melanocytes in blue nevi of all types express S100 protein, melan-A (MART-1), and gp100 (HMB-45).^{907,908} They do not stain for carcinoembryonic antigen (CEA).⁹⁰⁹ CD34 expression has been reported in a rare congenital form of cellular blue nevus with spindle-shaped cells, suggesting some overlap with neurocristic cutaneous hamartoma (see later).⁹¹⁰

Electron microscopy

Melanosomes are present in both the dendritic melanocytes and the paler cells of the cellular blue nevus. Some authors have highlighted schwannian features in this variant of blue nevus.⁹¹¹

Differential diagnosis

Several problems can arise in connection with common blue nevi. The first is the resemblance of some cutaneous melanoma metastases to blue nevi of conventional or epithelioid types. This is discussed further in the following section. The hypomelanotic blue nevus can resemble other spindle cell tumors, including dermatofibroma, neurofibroma, or scar. Fontana–Masson staining may reveal subtle melanin pigment not appreciated in H&E-stained sections, and the cells stain with other melanocytic markers, including S100, HMB-45, and Mel-5. Sclerotic lesions may be confused, clinically or microscopically, with desmoplastic melanomas or other types of melanoma with regressive changes. This has been underscored in a report of dermoscopic findings in a sclerosing cellular blue nevus; these included polychromasia – light and dark brown patches and grayish, white, and pink colors.⁴⁴⁷ However, these lesions lack significant nuclear pleomorphism or mitotic activity, and desmoplastic melanomas typically lack HMB-45 staining. Mihm and colleagues proposed the concept of *atypical cellular blue nevus* for a lesion that has clinicopathological features intermediate between typical cellular blue nevus and the rare malignant blue nevus.⁹¹² No metastases were recorded. The lesions were characterized by architectural and/or cytological atypia including necrosis.⁹¹² No atypical mitoses were present, indicating the importance of this finding in the distinction from malignant blue nevus.⁹¹² One interobserver study, involving experienced dermatopathologists, found a lack of consensus for the diagnosis of lesions thought to be cellular blue nevi, atypical cellular blue nevi, or malignant blue nevi.⁹¹³ This paper also reviews the criteria proposed by various authors for the diagnosis of atypical cellular blue nevus.⁹¹³ Recent molecular data suggest that chromosomal abnormalities (by CGH) are more predictive of an aggressive tumor biology and poor patient outcome than proliferative activity or specific genetic mutations (*BRAF*, *NRAS*, *KRAS*, *GNAQ/11*) in borderline lesions.⁹¹⁴ FISH analysis can also be used to distinguish cellular blue nevus from blue nevus-like melanoma. In one study, all of the melanomas showed chromosomal abnormalities, including gains in 6p25 and/or 6q23 losses, whereas none of the cellular blue nevi met criteria for melanoma.⁹¹⁵

BLUE NEVUS-LIKE METASTATIC MELANOMA

One of the most difficult diagnostic problems in dermatopathology is the recognition of the rare form of metastatic melanoma that closely simulates a blue nevus.^{916,917} The lesions usually occur in the same anatomic region as the primary tumor, but if no clinical history of a previous melanoma is provided, it is virtually impossible to make the diagnosis. Another problematic scenario is presented by the ocular melanoma with blue nevus-like metastases to distant cutaneous sites.⁹¹⁸

Histopathology

The lesions are composed of pigmented melanocytes and melanophages in a blue nevus-like growth pattern.⁹¹⁷ Atypical epithelioid

Figure 32.30 (A) Blue nevus-like melanoma. (B) There is a lymphocytic infiltrate at the edge of a lesion that closely resembles a blue nevus. (H&E)

melanocytes and mitotic figures are often present. In the author's experience, the presence of an associated inflammatory reaction at the periphery of the lesion is sometimes the only clue to the diagnosis (Fig. 32.30).

Differential diagnosis

In addition to nuclear pleomorphism, mitotic activity, and inflammatory reaction (features favoring melanoma), FISH studies can also be helpful. Differentiating chromosomal aberrations can be found in metastatic lesions, especially gains in 6p25 relative to centromere 6.⁹¹⁹ In another case, FISH analysis showed monosomy of chromosome 3 in both the primary uveal melanoma and the blue nevus-like metastatic lesion on the forehead; other chromosomal abnormalities detected included deletion of 1p36 and amplifications of 8q32.⁹²⁰

MALIGNANT BLUE NEVUS

Malignant blue nevus is an exceedingly rare, aggressive tumor found on the scalp, face, buttocks, and chest.^{921,922} It affects middle-aged to elderly patients, with a slight male predominance.⁹²³ Rare cases in childhood have been reported.⁹²⁴ If brain 'metastases' are present in childhood cases, it may raise the possibility that the brain lesions are actually a component of neurocutaneous melanosis.⁹²⁵ The term is

sometimes restricted to tumors arising in blue nevi with no concurrent junctional component, but it may be used for tumors that arise in a nevus of Ota⁹²⁶ or *de novo*.⁹²⁷ It usually arises in a cellular blue nevus. A malignant deep sclerosing blue nevus has been reported.⁹²⁸ In one case, the malignant blue nevus developed in a congenital disseminated blue nevus in a patient with the aromatase excess syndrome (OMIM 139300).⁹²⁹ Nodal metastases and distant metastases, particularly to the lungs, have been reported in malignant blue nevi.⁹³⁰⁻⁹³⁴ In one series of 12 cases (8 of which were on the scalp), metastases developed in 10, and 8 died of their metastases.⁹²³ Metastases may not develop for many years.⁹³⁵

Histopathology

There is usually an underlying blue nevus, in which a poorly circumscribed cellular nodule occupies a variable proportion of the lesion. The diagnosis is made by finding cytological features of malignancy, such as nuclear pleomorphism and atypical mitoses, combined with subcutaneous invasion and often some necrosis. The presence of atypical mitoses appears to be a more specific feature of malignancy than necrosis. Cytoplasmic vacuolization is often present in malignant lesions. A cellular blue nevus will often extend into the subcutaneous fat, but on low magnification it has a rounded, non-infiltrating pattern that is quite distinct from that seen in the malignant blue nevus. Furthermore, recurrence is a rare phenomenon in blue nevi. Cytological atypia and frequent mitoses may be seen, but necrosis and atypical mitoses are usually absent, distinguishing such cases from malignant blue nevus.⁹³⁶ The distinction from other types of melanoma, particularly metastatic melanoma, is aided by the absence of junctional activity and the presence of dendritic melanocytes.

AgNOR counts (see p. 890) and immunostaining for PCNA and Ki-67 (MIB-1) are useful additional parameters for the diagnosis. Both are significantly different from that seen in benign nevomelanocytic lesions.^{937,938} FISH and CGH studies may be useful for distinguishing blue nevi from malignant counterparts.^{914,919,939}

Cells resembling those found in a blue nevus may be found in the capsule of lymph nodes, either as an isolated phenomenon^{940,941} or in association with a cellular blue nevus.⁹⁴² Migration arrest during embryogenesis has been favored over 'benign metastasis' in explanation of this lesion.⁹⁴³ Metastases from a malignant blue nevus will usually involve much of the node.

Differential diagnosis

In a small study of malignancy arising from neurocristic hamartoma, staining for CD117 was strongly positive in both primary lesions and lymph node metastasis, although there was a lack of *KIT* mutations.⁹⁴⁴ A lack of *BRAF*, *NRAS*, and *GNAQ* mutations was also found, suggesting that this tumor might be distinct from malignant blue nevus and conventional melanoma.⁹⁴⁴

DERMAL MELANOCYTE HAMARTOMA

Dermal melanocyte hamartoma (dermal melanocytosis) is a very rare condition characterized by areas of diffuse gray-blue pigmentation or coalescing macular lesions, present at birth, and with similarities to the nevi of Ota and Ito (discussed previously).⁹⁴⁵⁻⁹⁴⁷ A segmental distribution of the pigmentation has been reported.⁹⁴⁸ In one case, the lesion involved the palm of a child.⁹⁴⁹ Related entities are the pilar neurocristic hamartoma^{950,951} and phakomatosis pigmentovascularis, in which there is a disorder of pigmentation associated with vascular abnormalities (see later). A rare acquired variant of dermal melanocytosis (**acquired dermal melanocytosis**) has been reported.^{952,953} In one report, the cases had symmetrical spotted pigmentation on the face and extremities,⁹⁵⁴ and in others localized lesions have developed.⁹⁵⁵ The trunk may also be involved.⁹⁵⁶ Its onset in pregnancy has been

recorded.⁹⁵⁷ Hori nevus (see p. 859) is one variant of acquired dermal melanocytosis.

Histopathology

In both dermal melanocyte hamartoma and phakomatosis pigmentovascularis, there are moderate numbers of dendritic melanocytes scattered throughout the upper and mid dermis, similar to the macular areas of the nevus of Ota.⁹⁵⁸ In one case of congenital dermal melanocytosis, there was also basal pigmentation of the epidermis.⁹⁵⁹ In the pilar neurocristic hamartoma, the pigment-laden spindle cells have a perifollicular arrangement similar to that of equine melanotic disease.^{902,950} In **acquired dermal melanocytosis**, the melanocytes are usually more dispersed in the dermis than in the blue nevus.⁹⁵⁵ Numerous melanophages are often present.⁹⁶⁰ There has been a question about whether acquired dermal melanocytosis and acquired bilateral nevus of Ota-like macules might be part of the same disease spectrum. A recent study comparing the histopathologic features of the two found that there are no significant differences in terms of degree of melanin pigmentation, numbers of melanocytes per unit area, or relative depth of melanocytes.⁹⁶¹

PHAKOMATOSIS PIGMENTOVASCULARIS

Phakomatosis pigmentovascularis (PPV) is a rare congenital syndrome with the combination of vascular anomalies, usually a large nevus flammeus, combined with cutaneous pigmentary abnormalities.^{958,962-975} The vascular lesions may take the form of the Sturge-Weber or Klippel-Trenaunay syndromes.⁹⁷⁶⁻⁹⁸¹ Association of PPV with a Klippel-Trenaunay and Sturge-Weber overlap syndrome has been reported.⁹⁸² Venous hypoplasia has also been described.⁹⁸³ Four subtypes have been recognized on the basis of the accompanying pigmented lesion and the presence of systemic or localized disease. A fifth type (type V) with cutis marmorata and dermal melanocytosis was added in 2003.^{984,985} Most cases have been reported from Japan. The pigmented lesions described include speckled lentiginous nevus (nevus spilus; **Fig. 32.31**),^{986,987} Mongolian spots, nevus depigmentosus, blue nevus, and nevus of Ota.^{988,989} Vitiligo and Lisch nodules are rare associations.^{990,991}

In 2005, Happle reclassified PPV, eliminating the traditional type I and placing the traditional type IV cases in the group of unclassifiable forms.⁹⁷³ The revised classification is shown in **Table 32.2**. Bilateral temporal triangular alopecia has been reported in the type IV (unclassifiable) category of phakomatosis pigmentovascularis.⁹⁹²

Figure 32.31 Nevus spilus (speckled lentiginous nevus) occurring in a patient with PPV. (H&E)

Table 32.2 Revised classification of phacomatosis pigmentovascularis

Type of phacomatosis	Type of coexistent nevi	Traditional name
Cesioflammea	Mongolian spots, dermal melanocytosis, and nevus flammeus	PPV type IIa/b
Spilorosea	Speckled lentiginous nevus (nevus spilus) and telangiectatic nevus resembling a salmon patch	PPV type IIIa/b
Cesiomarmorata	Mongolian spot(s), cutis marmorata	PPV type Va/b
Pigmentovascularis, unclassified type	Various types of vascular and pigmentary nevi	PPV type IVa/b, and no name

Note: The spelling of ‘phacomatosis’ follows that used by Happle in *Arch Dermatol* 2005; 141: 385–388. In his view, this spelling is preferable when ‘the term is followed by a Latin adjective’.

The genetic model explaining PPV is twin spotting (didymosis), which results from the cells’ loss of genetic heterozygosity.⁹⁸⁴ Twin spots are two different cutaneous lesions that are adjacent to one another and formed by mutant tissues that also differ from the rest of the normal tissue surrounding them.⁹⁸⁴

A related ‘twin nevus’ syndrome is **phacomatosis pigmentokeratotica**, a distinct type of epidermal nevus syndrome (see p. 951) characterized by the coexistence of an organoid nevus with sebaceous differentiation arranged usually along Blaschko’s lines and a speckled lentiginous nevus.^{993–995} There are often associated anomalies including hypophosphatemic vitamin D-resistant rickets.^{996,997}

CUTANEOUS NEUROCRISTIC HAMARTOMA

Cutaneous neurocristic hamartoma is composed of nevomelanocytes, pigmented spindle and dendritic cells, and Schwann cells.⁹⁹⁸ These hamartomas are often present at birth, but they may develop in childhood or adolescence. The lesions, which resemble blue nevi or congenital nevi clinically, average 3–7 cm in diameter. The scalp is a common site of involvement;^{999–1001} one case presented as cutis verticis gyrata.¹⁰⁰² The pilar neurocristic hamartoma can also be included in this concept (discussed previously). They are of presumed neural crest origin.¹⁰⁰³ Cases with overlap features of plaque-type blue nevus and neurocristic hamartoma have been reported.^{1004,1005}

There is a high incidence of malignant transformation, but the melanomas that develop run a more indolent course than common melanoma or melanoma arising in a blue nevus.⁹⁹⁸ They have been regarded by some¹⁰⁰⁶ as similar to animal-type melanomas (pigmented epithelioid melanocytomas) – see page 898.

Histopathology

Cutaneous neurocristic hamartoma most resembles a congenital nevus with neuroid features. There is a variable admixture of nevomelanocytes, Schwann cells, and dendritic blue nevus cells. Dermal hyper-neury has also been present.¹⁰⁰⁵ The hamartomas involve the dermis and can extend into the subcutis and skeletal muscle.¹⁰⁰⁷

The melanomas that may develop are subepidermal, often multinodular tumors composed of small, round to spindle cells displaying a trabecular or nested growth pattern. Nuclear palisading and perivascular pseudorosettes are sometimes present.⁹⁹⁸ The cells express S100 protein and vimentin; in a majority of cases, they also stain for HMB-45 and neuron-specific enolase.⁹⁹⁸

PARAGANGLIOMA-LIKE DERMAL MELANOCYTIC TUMOR

This term was introduced in 2004 to describe eight cases of a unique dermal melanocytic tumor that was distinct from cellular blue nevus, clear cell sarcoma, and cutaneous melanoma.¹⁰⁰⁸ All tumors had a nested pattern.

Follow-up information indicated that all patients were alive without disease after a period of 35–92 months (mean, 54 months).¹⁰⁰⁸ FISH analysis of five cases revealed no translocation, thus excluding clear cell sarcoma. Based on the follow-up and the morphology, this tumor is thought to be benign.

Histopathology

This dermal tumor was composed of nests of clear to amphophilic oval cells separated by delicate fibrous strands.¹⁰⁰⁸ Nuclear atypia was mild and mitotic activity low. Highly branched intratumoral vessels are present, which contribute to the descriptive term ‘paraganglioma-like’.¹⁰⁰⁹ Tumor cells expressed S100 protein and HMB-45. They lacked pancytokeratin and smooth muscle actin.¹⁰⁰⁸ Four of the eight cases expressed melan-A. The vessels are CD34⁺, and in one case, there were numerous Ki-67⁺ endothelial cells.¹⁰⁰⁹

ATYPICAL NEVOMELANOCYTIC LESIONS

DYSPLASTIC (ATYPICAL, CLARK’S) NEVUS

Dysplastic (atypical, Clark’s) nevi are clinically distinctive nevi with characteristic histology, and individuals with these nevi have an increased risk for melanoma (see p. 867).^{265,526,1010–1012} One or more dysplastic nevi can be found in 2–18% of the population.^{1013,1014} They are uncommon in the Japanese.¹⁰¹⁵ They constitute approximately 10% of the nevomelanocytic lesions received by one pathology laboratory.¹⁰¹⁶

The term ‘dysplastic (atypical) nevus syndrome’ refers to the familial or sporadic occurrence of multiple dysplastic (atypical) nevi in an individual.¹⁰¹⁷ Familial cases of this syndrome were originally called the B-K mole syndrome¹⁰¹⁸ (based on the surnames of two of the probands) and the familial atypical mole malignant melanoma (FAMMM) syndrome (OMIM 155600).¹⁰¹⁹ Controversy surrounding the use of the term ‘dysplastic’ in the title has led to the suggestion that the term ‘atypical mole syndrome’ is more appropriate.^{1020–1022}

Despite repeated calls, some quite strident, for the diagnosis of dysplastic nevus to be dropped,^{1023–1026} the diagnosis survives because proponents for its continued use can still be found^{1027–1029} and because alternative designations and definitions lack general support. The use of the term ‘Clark’s nevus’ as a synonymous term ignores its origin; the term was used by Ackerman for a nevus with architectural atypia in the form of a junctional shoulder extending beyond the dermal one.¹⁰³⁰ Lentiginous nevi are ‘captured’ by this definition. The suggestion of the second NIH Consensus Conference – ‘nevus with architectural disorder’ – had no chance of acceptance because it lacked brevity. However, some pathologists use this term.¹⁰³¹ ‘Nevus with architectural disorder and cytological atypia’ will suffer the same fate.¹⁰³² Glusac’s tongue-in-cheek contribution is LEJC-BFV nevus (lateral extension of the junctional component – bridging, fibrosis, nuclear variability).¹⁰³³ A small minority of dermatologists and dermatopathologists in the United States use the term Clark’s nevus.¹⁰³² It is probably even smaller in other countries.¹⁰³⁴

Clinically, dysplastic (atypical, Clark’s) nevi are usually larger than ordinary nevi (>5 mm in diameter), and they often show a mixture of tan, dark brown, and pink areas.^{1035,1036} Nonpigmented variants and agminated lesions are rare.^{1037–1039} There is often persistence of a

somewhat indistinct peripheral macular area in a lesion that, by its size, would be expected to be solely papular.¹⁰⁴⁰ The surface texture is often 'pebbly'. Not all nevi with these clinical characteristics have the histological features of dysplastic (atypical) nevi (see later).

In patients with the dysplastic (atypical) nevus syndrome, the number of nevi is large – up to 80 or more. In childhood, nevi usually appear normal; the abnormal lesions appear in adolescence and adult life.¹⁰⁴¹ The incidence of dysplastic nevi in the pediatric population is extremely low,¹⁰⁴² although a significant number of cases on the scalp and forehead were reported in one study of children younger than 18 years of age.¹⁰⁴³ Atypical nevi may continue to appear in up to 20% of patients older than age 50 years.¹⁰⁴⁴ However, many of those in adults with the syndrome are not of dysplastic (atypical) type: there are many junctional lentiginous nevi and compound melanocytic nevi.¹⁰⁴⁵ Persistence of junctional activity is a feature of most nevi in this condition, even in late adult life.¹⁰⁴⁶ Dysplastic (atypical) nevi predominate on the trunk. In females, there may be considerable numbers on the legs as well.¹⁰⁴⁷ There is evidence that sunlight induces the formation and enlargement of nevi in patients with the dysplastic (atypical) nevus syndrome,^{1048–1053} although this has been disputed.¹⁰⁵⁴ Dysplastic nevi in pregnancy may undergo a change in appearance.³⁸¹ Tattoos, if superimposed on nevi, can interfere with the surveillance of nevi in patients needing careful, long-term follow-up.¹⁰⁵⁵

In familial cases, the inheritance of the melanoma trait is autosomal dominant with incomplete penetrance. The dysplastic (atypical) nevus trait has a more complicated inheritance, occurring more commonly than is usual for dominant inheritance. Mutations in a gene on chromosome 9p21 (*CDKN2A*) have been found in patients with familial melanoma,¹⁰⁵⁶ but mutations in the *CDKN2A* gene are uncommon in dysplastic nevi.^{1057,1058} Interestingly, the dysplastic (atypical) nevus syndrome has also been associated with partial deletion of chromosome 11¹⁰⁵⁹ and with deletion of 17p13 (p53).¹⁰⁶⁰ A more recent study of patients with the syndrome failed to find sequence alterations in the coding regions or in the splice junctions of *CDKN2A*, *ARF*, *CDK4*, *PTEN*, or *BRAF*.¹⁰⁶¹ The genetic defect for many individuals with this syndrome remains unknown.¹⁰⁶¹ Intraocular melanomas,¹⁰⁶² oral melanoma *in situ*,¹⁰⁶³ other tumors (particularly pancreatic),¹⁰⁶⁴ and endocrine abnormalities¹⁰⁶⁵ have been reported in families with the dysplastic (atypical) nevus syndrome, but one study showed no increase in cancers other than malignant melanoma.¹⁰⁶⁶ The association with pancreatic carcinoma develops in patients with the dysplastic (atypical) nevus syndrome and *CDKN2A* mutations.¹⁰⁶⁷ A recent summary of molecular aspects of dysplastic nevi noted the following: (1) dysplastic nevi, like most common nevi, are clonal; (2) dysplastic nevi have *BRAF* mutations similar to common nevi but only rarely have *RAS* mutations; (3) some dysplastic nevi have alterations in p16 or p53 expression; (4) *PTEN* expression is lost in some dysplastic nevi but also in some common nevi; (5) microsatellite instability is seen in some melanomas and some dysplastic nevi but not in common nevi, and some dysplastic nevi have deletions in the p16-encoding chromosomal region 9p21; (6) dysplastic nevi have higher proliferation rates (by measures such as Ki-67 and cyclin D1 expression) than common nevi but lower than melanoma; (7) there is currently no evidence that dysplastic nevi are more resistant to apoptosis than common nevi; and (8) dysplastic nevi may show higher levels of oxidative stress than common nevi.¹⁰⁶⁸

It has been calculated that for a white resident in the United States, the lifetime risk of developing a melanoma is 0.6%, whereas in patients with dysplastic (atypical) nevi, this risk is 10% or more.^{1069–1074} The risk exceeds 50% in melanoma-prone families with the dysplastic (atypical) nevus syndrome.¹⁰⁷⁵ Blood relatives of patients who have had a melanoma or dysplastic (atypical) nevus removed also have an increased risk of developing a dysplastic (atypical) nevus^{1076,1077} or melanoma.¹⁰⁷⁸ Recent work suggests that approximately 25% of sporadic dysplastic (atypical) nevi harbor high-risk mucosal human papillomavirus genotypes.¹⁰⁷⁹

A rare clinical presentation of dysplastic (atypical) nevi is an eruptive form; it has been reported in a patient with AIDS,¹⁰⁸⁰ in one with chronic myelocytic leukemia,¹⁰⁸¹ in a patient who received chemotherapy for leukemia,¹⁰⁸² and following renal transplantation.¹⁰⁸³ A sporadic dysplastic (atypical) nevus has been reported in association with an adjacent neurofibroma.¹⁰⁸⁴ Dysplastic (atypical) nevi localized to one area of the body have also been reported.¹⁰⁸⁵

Several types of dysplastic (atypical) nevus can be discerned on dermoscopy.^{1086,1087} Nevertheless, there are currently no digital dermoscopic criteria that can clearly distinguish dysplastic nevi from *in situ* melanoma.¹⁰⁸⁸ The presence of globules appears to be a risk factor for the development of melanoma in dysplastic nevi.¹⁰⁸⁹

Treatment of dysplastic nevi

There is no place for the wholesale removal of multiple dysplastic nevi in patients with the dysplastic nevus syndrome. Nevi should be removed on the basis of their individual clinical features, if they are suspicious in any way. Because approximately one-third of all dysplastic (atypical) nevi are heterogeneous in their degree of atypia, incisional biopsy is *not* recommended. If such a lesion warrants a biopsy, it should be a complete excisional biopsy (which can include shave or punch) to allow complete sampling of the lesion.^{1090–1092} The treatment of dysplastic (atypical) nevi with imiquimod 5% cream for 12 weeks has failed to cause resolution of the nevi.¹⁰⁹³ The nevi showed more histological atypia than prior to treatment.¹⁰⁹³ A survey of fellows of the American Academy of Dermatology found that 67% of respondents prefer to re-excise dysplastic nevi when margins are positive.¹⁰⁹⁴

Sun protection is essential in the ongoing management of these patients. The detailed and thoughtful review of the subject by Duffy and Grossman concludes with the recommendation that although suspicious lesions should be removed, dysplastic nevi are fundamentally variants of common nevi; as such, most dysplastic nevi do not need to be re-excised following biopsy, although those with severe dysplasia or that cannot be distinguished from melanoma should be re-excised with assurance of clear margins.¹⁰⁶⁸

Histopathology^{1040,1095–1097}

Dysplastic (atypical) nevi, as originally defined, have three characteristic histological features: intraepidermal lentiginous hyperplasia of melanocytes, random cytological atypia of these cells, and a stromal response.^{1017,1040,1098} A fourth feature, architectural atypia, is generally regarded as a diagnostic requirement.¹⁰⁹⁹ *Lentiginous hyperplasia* refers here to a proliferation of melanocytes singly but also in nests along the basal layer. The nests may involve the sides of the elongated rete ridges as well as the tips (**Fig. 32.32**); bridging nests also form. The term 'junctional nest disarray' has been applied to the uneven distribution and pattern of the junctional component.^{1100,1101} The cells commonly show shrinkage artifact, with scant cytoplasm and a spindle-shaped pattern, but in some lesions there are larger cuboidal (epithelioid) cells with dusty pigment.

Random cytological atypia refers to the presence of occasional cells with enlarged hyperchromatic nuclei, sometimes with prominent nucleoli. The nuclei equal the nucleus of the overlying keratinocytes in size or are larger.¹¹⁰² The atypia is usually graded into low grade and severe, although there are no universally acceptable criteria for this.¹¹⁰¹ There is often a progression of cytological atypia with increasing age of the patient.¹¹⁰³ Furthermore, increasing atypia has been found to correlate with increasing darkness and confluence of pigmentation clinically.¹¹⁰⁴ Several reports have implied that severe atypia is associated with an increased risk of melanoma change, but this was not confirmed in one study.^{1105–1107} Atypia may also be present in nevi that do not otherwise fulfill the criteria for the diagnosis of a dysplastic (atypical) nevus.^{1108,1109} An example of this is the lesion described by Sachdeva *et al.* as '*de novo* intraepidermal epithelioid melanocytic

Figure 32.32 Dysplastic nevus. (A) There is a lentiginous proliferation of melanocytes in the basal layer, with some nests of nevomelanocytes in the junctional zone and in the dermis. Only mild cytological atypia is present. (B) There is mild fibroplasia involving the papillary dermis. (H&E)

dysplasia' characterized by a pagetoid array of moderate to severely atypical epithelioid melanocytes.¹¹¹⁰ It is a marker of the dysplastic (atypical) mole phenotype. The authors rejected the notion put forward in subsequent correspondence that this 'entity' was melanoma *in situ*.^{1111–1113}

The *stromal response* consists of lamellar and concentric fibroplasia of the papillary dermis, associated with a proliferation of dermal dendrocytes. Sometimes there is fibrosis in the upper reticular dermis, resulting in more widely spaced nests, often larger than usual. Such cases can be worrisome; they are often received in consultation (Fig. 32.33). There is also a patchy superficial lymphocytic infiltrate¹⁰⁴⁰ and, sometimes, new vessel formation. Neutrophils have been described around some of the epidermal and dermal melanocytic nests in a few cases.¹¹¹⁴

Ackerman and others have placed emphasis on *architectural atypia* rather than cytological atypia in defining a dysplastic (atypical, Clark's) nevus. They stress the importance of the 'shoulder phenomenon' (peripheral extension of the junctional component beyond the dermal component) in making the diagnosis.^{1106,1115,1116}

A dermal nevus cell component is usually present in the central part of the lesion, consisting of small cells or epithelioid cells but showing only slight evidence of maturation and with impairment of pigment synthesis. In other words, dysplastic (atypical) nevi are usually compound nevi with peripheral lentiginous and junctional activity and random cytological atypia in the epidermal component.

Toussaint and Kamino examined a large series of dysplastic nevi and found that the dermal component of some cases may show features of other varieties of nevi, such as a congenital nevus, Spitz nevus, blue nevus, halo nevus, or dermal neuronevus.¹¹¹⁷

Figure 32.33 Dysplastic nevus of compound type. There is fibrosis of the superficial dermis and an absence of nevomelanocytes in the overlying junctional zone, suggesting focal regression. Focal scarring of this type is not uncommon in dysplastic nevi. (H&E)

Figure 32.34 Dysplastic nevus. There is mild cytological atypia of the cells and mild fibroplasia of the papillary dermis. (H&E)

Several studies have assessed the inter- and intraobserver concordance in the diagnosis of dysplastic (atypical) nevi and the histological grading of their atypia. Although some centers have reported good reproducibility of results for both diagnosis and grading (into mild, moderate, and severe),^{1118–1121} others have reported limited or 'only fair' concordance for one or both of these features, particularly at the mild to moderate (low-grade) end of the spectrum.^{1122–1124} It is the author's practice to grade atypia in these lesions. It is accepted that interobserver concordance is sometimes poor, but it is hoped that an individual's grading of lesions is reasonably constant over time. Although there is usually agreement on the presence of architectural atypia, problems can arise in the assessment of cytological atypia (Fig. 32.34).^{1125–1127} Sometimes, lesions that display clinical features thought to indicate a dysplastic (atypical) nevus do not do so on histology.^{1128–1130} Conversely, some common nevi may show the histological features of a dysplastic nevus, leading to a suggestion that a continuum of cases exists.¹¹³¹ Some small junctional lentiginous nevi and nevi at special sites may exhibit some or all of the histological features of a dysplastic nevus.¹¹³² Color variegation often correlates with atypia, whereas the absence of a macular component clinically usually indicates a lack of atypia histologically.^{1133,1134} Another study found that nevus size and

irregular borders corresponded with the greatest number of individual histological parameters of a dysplastic (atypical) nevus.¹¹³⁵

Dysplastic (atypical) nevi have been reported in contiguity with up to one-third or more of superficial spreading melanomas.^{1136–1140} In determining whether a dysplastic (atypical) nevus is present, it has been proposed that the atypical lentiginous melanocytic hyperplasia should extend three or more rete pegs beyond the most lateral margin of the *in situ* or invasive melanoma.¹¹³⁷ Critics of this definition argue that the diagnosis of dysplastic (atypical) nevus is being applied indiscriminately in this and other situations.^{1141–1143} Dysplastic (atypical) melanocytes in an evolving melanoma *in situ* should not be regarded as indicative of a precursor dysplastic (atypical) nevus.

The AgNOR rating (see p. 890) of dysplastic (atypical) nevi is not significantly different from that of common nevi.^{1144–1147} Nuclei are usually diploid in type.¹¹⁴⁸ With immunoperoxidase techniques, S100 protein can be detected in the cells. However, the expression of gp100 (HMB-45) is limited to epidermal melanocytes and cells in the papillary dermis.^{1149–1151} The proteoglycan versican, which is strongly expressed in melanoma but not in benign nevi, is expressed variably in dysplastic (atypical) nevi.¹¹⁵² Versican has a role in the regulation of cell adhesion, migration, and differentiation of cells.¹¹⁵² The nucleic acid index, which detects derangements in nucleic acids at the level of the individual cells, is between that of melanoma and that of most benign nevi.¹¹⁵³ Increased expression of vascular endothelial growth factor A in dysplastic nevi appears to be a good indicator of preneoplastic change.¹¹⁵⁴

Electron microscopy

The melanosomes in epidermal melanocytes in dysplastic (atypical) nevi are abnormal, with incompletely developed lamellae and uneven melanization.^{1155,1156} The melanosomes are spherical. These abnormal melanosomes are transferred to keratinocytes before being completely melanized, and they reveal marked degradation.¹¹⁵⁵

LENTIGINOUS DYSPLASTIC NEVUS OF THE ELDERLY

This variant of dysplastic (atypical) nevus was described by Kossard and colleagues in 1991.¹¹⁵⁷ Kossard subsequently reinterpreted these lesions as nevoid lentigo maligna.¹¹⁵⁸ The term ‘pigmented lentiginous nevus with atypia’ is favored by Blessing.^{1159–1161} This entity is now regarded by some as lentiginous melanoma (see p. 887). Some still consider this an important precursor of melanoma and melanoma *in situ* in the elderly. The melanomas that develop are usually of superficial spreading type, but sometimes they are of indeterminate type, having overlapping features with lentigo maligna. This distinctive clinicopathological entity has been ignored until recently. Similar lesions have been categorized in the past (and presumably still are in most centers) as dysplastic nevus, atypical junctional nevus, melanoma *in situ* (early or evolving), and premalignant melanosis. ‘Field change’ adjacent to the original lesion is a common phenomenon unless adequate clearance (5 mm) is obtained.

Clinically, the nevi occur sporadically in individuals older than age 60 years. There is a predilection for the back in males and the legs in females. In females, the lesions often occur several decades earlier. There is usually some solar damage.

Histopathology¹¹⁵⁷

Lentiginous dysplastic nevus of the elderly is characterized by elongated rete ridges of uneven size and pattern in which there is extensive junctional nesting as well as single melanocytes. The nests are of irregular size and distribution. There is confluence of melanocytes over occasional single suprapapillary plates. The cells have hyperchromatic

nuclei with focal atypia. In some lesions, progression to melanoma *in situ* has occurred.

The dermis shows prominent lamellar fibrosis around the dermal papillae. There is a variable lymphocytic infiltrate and pigment incontinence. A small dermal component of nevus cells is sometimes seen.

MALIGNANT MELANOCYTIC LESIONS

This section discusses melanoma and rare entities with malignant or questionably malignant potential: *BAP1*-inactivated melanocytic tumors, pigmented epithelioid melanocytoma, clear cell sarcoma (melanoma of soft parts), melanocytoneuroma, and squamomelanocytic tumor. The malignant blue nevus has been discussed with its benign counterpart (see p. 861). The malignant lesion that may arise in a cutaneous neurocristic hamartoma is discussed on page 863.

MELANOMA

Incidence and mortality

The worldwide incidence of melanoma has increased significantly since the 1970s, currently accounting for 1.6% of all cancers (excluding non-melanoma skin cancers),¹¹⁶² with the most dramatic increase in the white populations of various industrialized countries.^{1163–1166} In the United States, the lifetime risk of developing a melanoma in 1987 was estimated to be 1 in 120; in 2000, it was 1 in 75; and in 2013, it was 1 in 35 for men and 1 in 54 for women.^{1167–1169} According to the National Cancer Institute’s Surveillance, Epidemiology, and End Results Program (SEER) facts, in 2013, there were approximately 76,690 new cases of melanoma diagnosed in the United States, with 9480 deaths.¹¹⁶⁶ These data correspond to an annual incidence of 27.4 (per 100,000 population) for men and 16.7 for women (rates are calculated from 2006–2010 data).¹¹⁶⁶ The highest annual incidence rates are in the subtropical state of Queensland in northern Australia: 83.4 in men per 100,000 population and 53.8 in women, equating to a lifetime risk of 1 in 11 and 1 in 18, respectively.¹¹⁷⁰ Similar rates are observed among white populations in Hawaii.¹¹⁷¹ The highest national incidence rates are in Australia and New Zealand, which are both countries with high ultraviolet exposure due to latitude and large white populations with outdoor lifestyles.^{1171–1173} The annual incidence per 100,000 population of various countries is listed in decreasing order: Australia, 62 (male) and 40 (female);¹¹⁷³ New Zealand, 39;¹¹⁷⁴ Switzerland, 19; Denmark, 18; Norway, 17; Sweden, 16; United Kingdom, 12; Germany, 12; Italy, 9; France, 8; Spain, 5; and Greece, 2.^{1171,1175} South America, Central America, Asia, and Africa (excluding South Africa, which is similar to European rates)¹¹⁷⁶ all have annual rates of melanoma well below the world average of 3 per 100,000 population.¹¹⁷¹ Large-scale immigration potentially can impact incidence data and may contribute to flattening incidence curves in select regions.¹¹⁷⁷ Incidence is also dependent on reporting efficacy.¹¹⁷⁸

In addition to geography/region, the incidence of melanoma varies by age, gender, ethnicity, and histologic subtype. Before age 40 years, the incidence is higher in women, with most melanomas occurring on the lower extremities and exhibiting the superficial spreading histology.¹¹⁷⁹ After age 40 years, the incidence is much higher in men, with most melanomas presenting on the head and neck.¹¹⁷⁹ The largest increase in incidence during the past several decades is among elderly white males,¹¹⁸⁰ and this increase is mirrored by the relative rise in the frequency of lentigo maligna and lentigo maligna melanoma histologic subtypes.¹¹⁸¹ Gender incidence differences and histologic subtypes of melanoma are likely attributed, in part, to patterns of UV exposure (including tanning salon use).¹¹⁸² The differences do not appear to be hormone related.¹¹⁸³ A recent Austrian study found that men have a higher incidence of melanoma than women and present with higher

stage tumors and have higher mortality, consistent with findings from other countries.¹¹⁸⁴ Incidence increases are most pronounced in white populations, whereas the incidence among darkly pigmented populations has risen only slightly or remained constant.¹¹⁶⁶ In the United States, African Americans and Hispanics present with higher stage melanomas and have a worse 5-year survival compared to white populations.^{1169,1185–1187} Superficial spreading melanoma has the highest incidence worldwide, but up to 50% of Japanese melanoma patients have the acral lentiginous subtype.¹¹⁸⁸ Melanoma incidence is increasing among pediatric populations.¹¹⁸⁹

Although the incidence of melanoma clearly has increased, mortality curves largely have remained flat.^{1162,1166,1170,1190} In the United States, the 5-year relative survival rate was 82% during 1975–1977, 88% during 1987–1989, and 91% during 2003–2009.^{1166,1170} High survival rates and flat mortality curves are, in part, attributable to more patients presenting at an earlier stage with smaller and therefore potentially curable lesions.^{1191–1198} Less favorable survival data outside of North America, western Europe, and Australia likely are attributable to more advanced stage tumors at diagnosis.¹¹⁷⁵ Recent therapeutic breakthroughs for advanced disease are promising, but their impact on long-term survival has yet to be realized.^{1199–1201} Cures remain almost exclusively surgical and in patients with low-stage tumors, but at diagnosis, low-stage tumors far outnumber advanced-stage tumors.¹¹⁶⁹ The divergence of incidence and mortality curves may be due to increased tumor surveillance and removal of early lesions as well as, in part, overdiagnosis of melanoma.^{1202–1204} Although these likely play some role, they cannot explain completely the recent dramatic rise in incidence because the number of patients presenting with advanced tumors appears to also be on the rise, suggesting a true increase in melanoma incidence.^{1202,1204–1207}

Melanoma is primarily a cutaneous disease, but a significant number of cases are reported each year in ocular (approximately 0.4–1.0 per 100,000 population worldwide)¹²⁰⁸ and mucosal (approximately 0.2–0.4 per 100,000 population)¹²⁰⁹ locations.¹¹⁶⁶ Unlike cutaneous melanoma, the incidence of extracutaneous melanoma has been fairly stable since the 1970s.^{1209,1210} There is a slightly higher increased (approximately twofold) incidence in extracutaneous melanomas among populations with light skin/eyes compared to more pigmented populations, but this difference is significantly less pronounced than with cutaneous melanomas.^{1209,1211} Of the ocular melanomas, most occur in the choroid, with the ciliary body and iris being less common locations. Primary mucosal melanomas are most common in the nasal cavity, sinuses, oropharynx, anorectum, vulva (including clitoris and labia), and vagina.¹²¹² Less commonly, melanomas can arise in the esophagus, stomach, small and large intestines, gallbladder, bile ducts, larynx, trachea, bronchi, lung, urethra, bladder, and cervix.¹²¹² Primary melanomas also rarely occur in the central nervous system, arising from melanocytes in the leptomeninges and usually involving the spinal cord.^{1213,1214} Primary intracranial^{1215–1217} and pineal gland^{1218,1219} melanomas also occur. Primary melanomas have also been reported in the prostate,^{1220,1221} salivary glands,^{1222,1223} kidney,¹²²⁴ thyroid,¹²²⁵ thymus,¹²²⁶ pancreas,¹²²⁷ ovary,^{1228,1229} and adrenal glands,^{1230,1231} with many cases likely arising in extensions of the mucosal network. It is unclear how many of these reported cases are true primary melanomas and not metastases with an occult primary. The incidence/existence of a primary melanoma arising in the soft tissues that is not the molecularly distinct clear cell sarcoma is currently unknown. In general, extracutaneous melanomas have a much worse prognosis than their cutaneous counterparts.^{1232,1233}

Risk factors

Genetic and environmental factors arguably play a role in the epidemiology of any disease, including melanoma. In the beginning of the nineteenth century, Dr. William Norris, a general practitioner in the United Kingdom, recognized this fact when he described a family with numerous moles and melanoma and subsequently described eight

Table 32.3 Risk factors for melanoma

Risk factors	Risk ^a
Clinical	
Five or more dysplastic nevi	10 RR
Previous melanoma	9 RR
>100 total nevi	7 RR
Red hair	4 RR
Family history	
One dysplastic nevus	
16–40 total nevi	
Light skin	1.5–2.5 RR
Light eyes	
Light hair	
Freckling	
Poor tanning ability	
Tanning bed use	
History of sunburns	
PUVA therapy, immunosuppression, exposures	^b
Genetic	
High risk	
<i>CDKN2A</i> mutation in high-risk families	0.91 (Australia) ^c 0.76 (United States) ^c 0.58 (Europe) ^c
<i>CDKN2A</i> mutation (unselected)	0.28 ^c
<i>CDK4</i>	(Same as <i>CDKN2A</i>)
<i>BAP1</i>	^b
<i>RB1</i>	4–80 RR
<i>XP (A-G)</i>	600–8000 RR
Intermediate risk	
<i>MC1R</i>	2.7 RR (one allele affected)
<i>MITF</i>	2.2 RR (E318K variant)
Low or unknown risk	
<i>ASIP, ATM, CASP8, CCND1, EDNRB, GSTM1, GSTP1, IRF4, MTAP, MX2, OCA2, PARP1, PLA2G6, SETDB1, SLC45A2, TERT, TYR, TYRP1, VASH2, VDR, others</i>	^d

^aRelative risk (RR) is defined as the risk of developing melanoma if the risk factor is present versus absent. A relative risk of 1.0 means there is no increase in risk. A relative risk of 2.0 means there is double the risk.
^bSufficient data not available.
^cPenetrance by age 80 years. A value of 1.00 means the patient has a 100% chance (cumulative risk) of developing melanoma by age 80 years.
^dRisk is low or unknown. The genes listed are either known to be associated with melanoma risk or considered candidate low-risk susceptibility genes located near single nucleotide polymorphisms identified by genome-wide association studies (GWAS).

melanoma patients, some with light hair, pale complexion, and possible industrial pollution exposure.^{1234,1235} Since then, a large body of literature weighing risk factors for melanoma has been compiled. With the exception of large numbers of dysplastic (atypical) or common nevi and certain germline mutations, which have a fairly high relative risk, most of these factors have a relative risk (RR) in the 1.5–2.5 range (Table 32.3).^{1165,1236}

Environmental and host factors

The most important environmental risk factor for melanoma is UV exposure, supported by the incidence data presented previously. Many

studies have examined the sun-exposure habits of patients with melanoma.¹²³⁷⁻¹²⁴² Although Ackerman has questioned the significance of a blistering sunburn,¹²⁴³ many studies have identified high, intermittent sun exposure (sunburning) as a significant risk for developing melanoma.^{1237,1241,1242} Many melanoma patients report a history of painful or blistering sunburns during childhood or adolescence,¹²⁴⁴ and two or more such episodes before the age of 15 appear to increase risk.⁸⁵ Other studies have suggested that a history of sunburns in adulthood also increases risk, independent of childhood exposure.^{1245,1246} Melanoma is more likely to occur in people living in more affluent suburbs, possibly reflecting the ability of these individuals to travel to locations that promote high intermittent sun exposure.¹²⁴⁷ Melanoma risk is increased in marathon runners, who also are intermittently exposed to high doses of UV radiation.¹²⁴⁸ A sample of 207,726 respondents in the United States, in 2003, found that 39% of respondents had at least one sunburn within the previous 12 months.¹²⁴⁹ UV index and lower altitude are significant risk factors for melanoma in non-Hispanic whites and, to a lesser degree, in Native Americans.¹²⁵⁰ UV exposure may also modestly increase the risk for melanoma in more darkly pigmented individuals (U.S. Hispanics and African Americans),¹²⁵¹ although this correlation is not firm.¹²⁵⁰

The role of chronic sun exposure is more controversial.^{1252,1253} Whereas some studies have suggested that total accumulated exposure to sunlight is an important risk factor, others have found that long-term occupational exposure to sunlight actually may be protective against melanoma.¹²⁵⁴ Outdoor activities in childhood appear to be associated with a slightly lower risk of melanoma.¹²⁵⁵ In a recent study analyzing data from two multicenter population-based case-control studies, occupational (chronic) sun exposure had little or no effect on melanoma risk, independent of anatomic site.¹²⁵⁶ Several studies, including a large meta-analysis of the relationship between UV exposure and melanoma risk, revealed a modestly increased risk with high total UV exposure (RR 1.3)¹²⁴¹ compared to a significantly higher risk with intermittent sun exposure (RR 2–2.5, with most northern latitudes having the highest risk).^{1241,1257,1258}

Sunscreen use has a clear role in UV protection, but its impact on melanoma incidence is less clear. Studies have demonstrated a positive correlation between sunscreen use and a decrease in melanoma incidence, but other studies have shown no correlation or even a negative correlation.^{1259,1260} Conflicting data partially can be explained by the use of sunscreens modifying sun-exposure behavior, leading to sun exposures of greater duration.¹²⁶¹ Similarly, the wearing of sunglasses appears to adversely modify sun-exposure behavior.¹²⁶² These findings have important public health implications.^{1263,1264} Patient education remains of paramount importance if UV protection is going to have an objective, realized impact on melanoma incidence. Sun avoidance and sun protection remain the mainstays of melanoma prevention for persons at high risk because no clear choice for effective melanoma chemoprevention has emerged.¹²⁶⁵

In addition to natural UV exposure, artificial and iatrogenic UV exposures also increase the risk for melanoma. Patients who have received multiple PUVA exposures in the treatment of psoriasis and other conditions appear to have an increased risk of melanoma.¹²⁶⁶⁻¹²⁶⁹ For psoriasis patients, melanoma usually develops approximately 15 years after the first treatment.¹²⁶⁸ An emerging significant risk is the frequent use of tanning salons, leading to calls for stricter regulations of use in the United States and other countries.¹²⁷⁰⁻¹²⁷⁵ Women aged 45 years or younger carry the highest risk.^{21,1276,1277} The use of indoor tanning is associated with several different behavioral patterns, including addictive behavior in a subset of users.^{1278,1279} Moreover, knowledge of the risks of UV overexposure does not seem to elicit behavioral change.^{1280,1281} The biologic mechanisms of addiction, including activation of reward pathways in the brain, are shared between tanning and other addictive behaviors.¹²⁸² Left unchecked, promotion of tanning parlors likely will erode previous gains made in skin cancer control.¹²⁸³

The risk for melanoma is elevated modestly with only one tanning bed session (RR 1.25). The risk significantly increases with younger age of first exposure and repetitive use.¹²⁸⁴

Other environmental exposures associated with melanoma have been reported but are less well characterized, and in some cases, true causality has not been established. Reported associations include exposure to polyvinyl chloride,^{1285,1286} insecticides,¹²⁸⁷⁻¹²⁸⁹ chemical solvents,^{1290,1291} arsenic-polluted water,^{1292,1293} and redox-active metals (occupational exposures and/or joint replacements),¹²⁹⁴ among other exposures.¹²⁹⁵⁻¹²⁹⁷ Melanomas also have been reported following certain therapies, such as electron beam radiation for cutaneous T cell lymphoma,¹²⁹⁸ brain irradiation for anaplastic astrocytoma,¹²⁹⁹ radiotherapy for breast carcinoma,¹³⁰⁰ and levodopa therapy for Parkinson disease,¹³⁰¹⁻¹³⁰³ although it remains unclear whether melanoma is associated with these diseases or their therapies.^{1300,1304-1307} Voriconazole therapy may increase risk, possibly via increased photosensitivity.¹³⁰⁸ Melanomas occur 1.6 times more commonly in organ transplant recipients compared with the general population, and this is thought to correlate with immunosuppression.¹³⁰⁹⁻¹³¹⁶ Melanoma has been reported following transplants from donor organs with occult melanoma, raising concerns about voluntary organ donation from patients with any history of melanoma, no matter how remote.^{1317,1318} Immunosuppression by other means, including the use of biologics for treating psoriasis, rheumatoid arthritis, and inflammatory bowel disease, for example, may also increase risk.¹³¹⁹⁻¹³²² Differences in the incidence of melanoma by gender have raised the possibility of a risk associated with hormone replacement therapy¹³²³ or pregnancy,¹³²⁴ but this has not been substantiated.¹¹⁸³ In addition, the increased incidence of melanoma among aircraft crew members raised concern about the role of low-level cosmic ionizing radiation, but the risk appears more related to skin type and UV exposure in case-control studies.¹³²⁵⁻¹³²⁸

The risk for melanoma extends beyond environmental exposures, with the most significant risks originating from the host. Many host risk factors are related to UV sensitivity, with numerous studies demonstrating an increased risk of melanoma in populations with pale skin, blond or red hair, easy freckling, poor tanning ability, and a tendency to burn.^{1240,1329-1331} In a large meta-analysis of melanoma risk focusing on host phenotypic factors related to sun sensitivity, the following approximate relative risks were established: red hair (RR 3.6), light skin color (RR 2), freckling (RR 2), poor tanning ability (RR 2), light hair (RR 1.8), and light eyes (RR 1.5).¹³³² The presence of nevi is also a risk factor. Proneness to develop nevi correlates not only with sun exposure, including blistering episodes, but also with skin complexion, hair color, and tanning ability.⁸⁵ Large congenital nevi and dysplastic (atypical) nevi have been recognized as potential precursor lesions for some time.¹³³³⁻¹³³⁵ It is only comparatively recently that the etiological significance of large numbers of common (banal, typical), acquired nevi has been appreciated.¹³³⁶⁻¹³⁴¹ Two studies from Japan found that a large number of acquired nevi is a risk factor for non-acral melanoma, but acquired nevi on the soles, palms, and nail apparatus do not seem to be a risk factor for acral melanoma.^{1342,1343} The presence of numerous (>100), small, darkly pigmented nevi (the cheetah phenotype)¹³⁴⁴ and nevi greater than 6 mm in diameter¹³³⁹ appear to be independent risk factors. A large meta-analysis of nevi counts demonstrated the following approximate relative risks for melanoma: 5 or more dysplastic (atypical) nevi (RR 10), >100 total nevi (RR 7), and 1 dysplastic (atypical) nevus (RR 1.6).¹³⁴⁵

Although the risk of patients with numerous nevi and/or dysplastic (atypical) nevi developing melanoma is known, less is known of the transformation rate of melanocytic nevi into melanomas. A study from Boston published in 2003 estimated that the *annual* transformation rate of any single nevus into a melanoma ranges from 0.0005% or less (<1 in 200,000) for both men and women younger than 40 years to 0.003% (1 in 33,000) for men older than 60 years.¹³⁴⁶ The *lifetime risk* was estimated at 1 in 2000 in another study,¹³⁴⁷ compared to 1 in 3164

for men and 1 in 10,800 for women in the Boston study.¹³⁴⁶ Although the presence of numerous nevi increases the risk for melanoma, only approximately one-fourth to one-third of melanomas have histologic evidence of a concurrent nevus.^{1115,1348} Younger age, superficial spreading subtype, and truncal location are predictors of a melanoma being histologically associated with a nevus.¹³⁴⁸ Melanomas arising within a nevus of Ota,¹³⁴⁹ nevus of Ito,¹³⁵⁰ blue nevus,^{1351,1352} and nevus spilus^{1353–1356} have been reported but are considered extremely rare events.

Various other melanoma associations have been reported. Some of these may represent the chance occurrence of two conditions, whereas others are more firm as new genetic data are emerging. Melanomas have been reported in association with squamous cell and basal cell carcinomas,¹³⁵⁷ xeroderma pigmentosum (particularly complementation groups C and D),^{86,1358} albinism,^{1359–1362} retinoblastoma,^{1363–1366} Li–Fraumeni syndrome,¹³⁶⁷ pancreatic carcinoma,^{1368–1370} ocular melanoma,¹³⁷¹ mesothelioma,¹³⁷² meningioma,¹³⁷³ renal cell carcinoma,^{1374,1375} LEOPARD syndrome,¹³⁷⁶ Birt–Hogg–Dubé syndrome,^{1377–1379} Hailey–Hailey disease,¹³⁸⁰ Gorlin syndrome,¹³⁸¹ Cowden disease,¹³⁸² neurofibromatosis,^{1383,1384} Beckwith–Wiedemann syndrome,¹³⁸⁵ Lynch syndrome,¹³⁸⁶ pulmonary carcinoid,¹³⁸⁷ soft tissue sarcomas,^{1300,1388,1389} gastrointestinal stromal tumors,¹³⁹⁰ thyroid carcinoma,^{1226,1391} Merkel cell carcinoma,¹³⁹² mycosis fungoides,^{1393–1395} other leukemias and lymphomas,^{1396–1404} Castleman disease,¹⁴⁰⁵ systemic mastocytosis,¹⁴⁰⁶ bronchogenic cysts,¹⁴⁰⁷ cystic teratomas,¹⁴⁰⁸ epidermal inclusion cysts,¹⁴⁰⁹ phacomatosis pigmentovascularis,¹⁴¹⁰ Turner syndrome,^{1411,1412} Down syndrome,¹⁴¹³ Parkinson disease,^{1301,1302} Charcot–Marie–Tooth disease,¹⁴¹⁴ dermatomyositis (presumed paraneoplastic),^{1415,1416} erythema dyschromicum perstans,¹⁴¹⁷ sarcoidosis,¹⁴¹⁸ chronic inflammatory demyelinating polyneuropathy,¹⁴¹⁹ stasis dermatitis,¹⁴²⁰ chronic wounds/ulcers and lymphedema,¹⁴²¹ burn scars,^{1422,1423} cesarean skin scars,¹⁴²⁴ tattoos,^{1425–1428} other trauma (subungual melanomas),^{309,1429} lichen sclerosus of the vulva,^{1430,1431} epidermolysis bullosa simplex,¹⁴³² Marjolin ulcers,¹²⁹⁶ human papillomavirus infections (HPV 3, HPV 16, and subtypes associated with epidermodysplasia verruciformis),^{1433–1435} and infections with the human immunodeficiency virus.^{1436,1437} Patients with atopic dermatitis appear to have a lower risk of developing melanoma.¹⁴³⁸

Genetic factors

Approximately 10% of melanomas are familial, or hereditary, meaning there is a strong family history and/or a documented melanoma-related germline mutation. The majority of familial melanomas are inherited in an autosomal dominant manner. Family history is variably defined, but it typically includes a single first-degree family member or multiple more distant family members affected on the same side of the family. In an individual with a positive family history, the risk varies greatly depending on the circumstances. A positive family history equates to approximately a twofold risk in developing melanoma.^{1296,1439} However, patients with a documented *CDKN2A* mutation, with a family history, and living in Australia have a 91% cumulative risk of developing melanoma by age 80 years.¹⁴⁴⁰ Identification of individuals who harbor the mutation in the high-risk family has importance because they may develop melanoma at an earlier age, have a higher risk of developing a second primary melanoma, have a higher risk for other visceral malignancies such as pancreatic carcinoma, and may pass on their susceptibility gene to their offspring. All of these reasons introduce potential points of intervention by increased surveillance.

Melanoma susceptibility genes play roles in cell cycling, melanocyte development, and melanin biosynthesis. They can be subclassified into high-, intermediate-, and low-risk genes, and excellent reviews are available on this topic.¹⁴⁴¹ High-risk melanoma alleles are associated with multiple melanomas within family members, individuals with multiple melanomas, and early onset melanomas. Intermediate/moderate- and low-risk alleles may have a direct association with melanoma risk but more often are associated with pigmentary changes and light sensitivity, indirectly increasing the risk for melanoma.

High-risk loci

Of the high-risk genes, mutations in *CDKN2A* and *CDK4* are the most common.¹⁴⁴² In a recent study by the melanoma research consortium GenoMEL (North America, Europe, Australia, and the Middle East), of the 466 melanoma families studied, 41% had mutations in *CDKN2A* (40%) or *CDK4* (1%).¹⁴⁴² These data support *CDKN2A* and *CDK4* as attractive targets for studying the biology of hereditary melanoma and developing genetic tests, but they also highlight the fact that more than half of melanoma families have different or yet-to-be-determined molecular defects.

CDKN2A is the most studied locus in melanoma families, first reported in 1994.¹⁴⁴³ This gene, located on chromosome 9p21, was identified using linkage analysis on large melanoma families, and it is the primary locus involved in the well-characterized B-K mole and familial atypical multiple mole melanoma (FAMMM) syndromes.^{1018,1019} Patients with this autosomal dominant syndrome have an increased number of clinically atypical nevi, although it remains controversial whether these nevi are precursors to melanoma or merely connote higher risk for the development of melanoma elsewhere on the body. Germline *CDKN2A* mutations increase the risk for melanoma in patients without the FAMMM phenotype. In addition, numerous atypical nevi do not predict a germline *CDKN2A* mutation.^{1443,1444}

CDKN2A has overlapping coding regions for two distinct proteins, p16^{INK4a} and p14^{ARF}.^{1445,1446} These are both tumor suppressor genes involved in cell cycle regulation and apoptosis, respectively (see p. 871). There are many reported mutations in *CDKN2A*, primarily involving and spanning exons 1- α and 2, and thus primarily involving p16^{INK4a}. A few common mutations stand out, including 225–243del19 ('Leiden'), M53I ('Scottish'), and G101W. Each of these three mutations has been observed in more than 15 extended families worldwide. Of the known familial *CDKN2A* mutations in melanoma families, approximately 96% involve p16^{INK4a}, with the remaining 4% involving p14^{ARF}.¹⁴⁴²

Environmental factors, specifically UV radiation, appear to play a significant role in the development of melanoma in susceptible families. In a study on the risk of developing melanoma among carriers of *CDKN2A* defects from different geographies, by age 80 years, the penetrance is 0.58 for Europeans, 0.76 for Americans, and 0.91 for Australians.¹⁴⁴⁰ In addition, the penetrance is only 0.28 with unselected (familial and nonfamilial) *CDKN2A* germline mutations, suggesting a role of co-inherited factors.¹⁴⁴⁷ Mutations or variants in other melanoma risk genes (e.g., *MC1R*) may have an additive or synergistic effect on an individual's risk.^{1448,1449} In a separate study from Australia, individuals with both a *CDKN2A* mutation and a *MC1R* melanoma-associated variant had an 84% cumulative lifetime risk of melanoma versus 50% risk with the *CDKN2A* mutation alone.¹⁴⁴⁸ In addition, individuals with numerous nevi, poor tanning ability, and/or a propensity to sunburn within *CDKN2A* mutated families have an elevated risk for melanoma.^{1450,1451} Individuals within families with documented *CDKN2A* mutations have an increased risk of developing other cancers, primarily pancreatic cancer, with variable penetrance. Pancreatic cancers are not common in Australian families.¹⁴⁵² Families with pancreatic cancer have mutations in p16, not p14 or *CDK4*.^{1442,1453} Neural system tumors occur at an increased rate within families with documented *CDKN2A* mutations, and they have a loose association with mutations in the p14 region.¹⁴⁴² Breast cancer has been reported among individuals in Swedish melanoma-prone families, but the genetic relationship has not yet been established.¹⁴⁵⁴

Germline ***CDK4*** mutations in familial melanoma were discovered soon after *CDKN2A* mutations,¹⁴⁵⁵ and they account for approximately 1% of all familial melanomas.¹⁴⁴² Although less frequent than *CDKN2A* mutations, *CDK4* mutations carry an equally high risk for the development of melanoma and have a virtually identical clinical phenotype.¹⁴⁵⁶ The latter may not be surprising because the most common *CDK4* mutations, R24C and R24H, are found at the p16 binding region of the protein.¹⁴⁴¹

More recently, **BAP1** has been identified as a high-risk locus.¹⁴⁵⁷ An inherited inactivated **BAP1** allele is associated with the autosomal dominant **BAP1** hereditary cancer predisposition syndrome. These individuals are at high risk for uveal melanoma.¹⁴⁵⁸ They have an increased risk for cutaneous melanoma, renal cell carcinoma, mesothelioma, meningioma, lung adenocarcinoma, and other tumors, including atypical Spitzoid lesions, with variable penetrance.^{1457–1461} The cutaneous melanomas usually occur in the context of a patient with uveal melanoma.¹⁴⁶²

Other genes are linked to a high risk of melanoma but are altered at a much lower frequency than those described previously. The **XP** family of genes (mostly **XPC**), when mutated, has an astonishingly high risk for developing melanoma (RR 600–8000) in the context of xeroderma pigmentosum, but these mutations are extremely rare.¹³⁵⁸ Long-term survivors of retinoblastoma (**RB1** mutations) also have a high risk for melanoma.^{1462,1463}

Intermediate- and low-risk loci

Although the previously mentioned genes are associated with high-risk susceptibility for melanoma, mutations in these genes are relatively infrequent compared to all melanomas. Mutations and genetic variants at other loci are much more common in the general population and all melanomas but independently carry much lower risk for the development of melanoma.

MC1R is considered an intermediate-risk locus involved in melanin synthesis (see p. 867).¹⁴⁶³ **MC1R** variants can increase the risk for developing melanoma up to 2.7-fold.^{1165,1464} These variants can impact the relative balance of eumelanin and pheomelanin production, and therefore many are associated with the red hair phenotype. Some variants are associated with the red hair phenotype and an increased risk for melanoma, whereas other variants have increased risk for melanoma without the red hair phenotype, suggesting a more complex role for **MC1R**.¹⁴⁶⁵ The variants associated with the most significant risk of melanoma and the red hair phenotype include D84E, R142H, R151C, R160W, and D294H. Other variants, I155T and R163Q, are associated with an increased risk for melanoma but not the red hair phenotype. The variants with the most significant risk for melanoma are designated as 'R' or 'RHC' alleles. There are other variants, 'r' or 'rhc' alleles, that also increase risk, but to a lower degree (RR in the 1.5 range).¹⁴⁶⁴ Examples of low-risk alleles are V60L, V92M, and R163Q. Melanomas in patients with **MC1R** variants also have **BRAF** mutations.^{1466,1467}

MITF also is involved in melanin synthesis and is considered an intermediate-risk gene.¹⁴⁶⁸ Recently, the germline E318K mutation was linked to melanoma and renal cell carcinoma.^{1469,1470} **TERT** promoter mutations occur at a high frequency in sporadic melanomas and, recently, were identified in the germline of a melanoma-prone family.¹⁴⁷¹ Many other melanoma risk loci with putative susceptibility genes have been discovered using family based and genome-wide association studies (GWAS) (see Table 32.3).^{1472–1485} These studies are designed to identify common but low-risk susceptibility genes, and they have been performed on populations in Europe (Dutch, Swedish, Spanish, Icelandic, etc.), Australia, and North America. Many of these studies focus on linkage to hair and skin pigmentation, freckling, nevi, and/or direct linkage to melanoma, and they have identified single nucleotide polymorphisms (SNPs) near candidate genes. These candidates are currently under investigation to assess their role in the biology of melanoma and their true association with melanoma risk.

Genetic testing

The role of genetic testing is controversial, but the importance of genetic counseling in order for the individual to have a clear understanding about the true meaning of positive and negative test results is not controversial.¹⁴⁸⁶ Clearly, having the information can have some benefits to the individual, his or her family, and his or her physicians. A positive result potentially can identify individuals and family

members at high risk for melanoma, allowing consideration for more rigorous or frequent dermatologic screening. With a higher risk for pancreatic cancer in some populations (mainly Europeans and North Americans), these individuals may also benefit from rigorous screening for visceral disease, if such methods become more effective and available (i.e., ultrasound or CA19.9 blood levels).^{1369,1452} Testing can identify a family 'signature' mutation, which can be followed among subsequent offspring. Individuals who test positive for a family signature mutation will have a better understanding of their likelihood for the development of melanoma. In addition, those negative for their family signature mutation can be reassured that their risk is much lower (but not zero, given other potential genetic and environmental factors), thus alleviating potential psychological stress.

Of course, testing is not without its pitfalls. The false-negative rate is high because less than half of individuals from melanoma families will have a detectable mutation. Moreover, because most commercially available tests only screen the *p16^{INK4A}* regions of **CDKN2A**, individuals with negative results may have other known but undetected melanoma-associated germline mutations (e.g., **CDKN2A** exon 1β for *p14^{ARF}*, **CDKN2A** intron defects, and **CDK4** mutations). Negative results also may have unintended consequences, such as increasing the risk for sporadic melanomas in individuals who test negative and subsequently abandon practices to limit UV exposure. Because **CDKN2A** mutations occur with relative frequency in certain populations and are not uniformly drivers of melanoma (silent mutations, for example, not associated with melanoma), without a known family signature mutation, these results must be interpreted with caution because there could be a different melanoma-causing gene. There are also the usual concerns with genetic testing, including but not limited to cost, insurance coverage, and genetic discrimination.

In an unscreened population, only 1% of individuals will test positive for a **CDKN2A** mutation, and this rate varies widely depending on geography.¹⁴⁸⁷ This raises the typical concerns regarding tests with a low pretest probability, and this approach is not recommended. There may be an argument to test certain subgroups, however. The likelihood (and therefore pretest probability) that a patient from a melanoma family has a **CDKN2A** mutation increases with the number of primary melanomas, the number of family members affected, and the presence of pancreatic cancer in the family. This is enhanced even more if the patient is from a geographic region with a low incidence of melanoma because areas with a high incidence are significantly diluted by nonfamilial cases. Germline **CDKN2A** mutations in melanoma families are relatively less common in regions with a higher total incidence of melanoma: Europe (57%), North America (45%), and Australia (20%).¹⁴⁵² A family history of melanoma is the strongest predictor of a **CDKN2A** mutation, with approximately 40% of families harboring a detectable mutation.¹⁴⁸⁸ In patients with multiple primary melanomas, 2.9% have detectable germline mutations.¹⁴⁸⁷ To maximize the utility of genetic testing for melanoma, algorithms have been proposed based on these aforementioned factors. One proposed method of screening is to test only the following: individuals with three or more cutaneous melanomas *or* patients with a strong family history including at least one invasive melanoma *and* two or more diagnoses of melanoma *and/or* pancreatic carcinoma among first- or second-degree relatives.¹⁴⁸⁶ Other similar algorithms are available, and the stringency of the criteria for testing may be loosened if the patient is from a low-risk geographical zone.¹⁴⁸⁹

Pathogenesis

Melanoma is not a single entity but, rather, a genetically heterogeneous group of tumors, which are tied together only by the common bond of originating within a melanocyte. Recently, the identification of key signaling molecules and pathways within the melanocyte has helped shape current concepts of melanomagenesis. External factors, mutations, and epigenetic events all contribute to melanomagenesis. Recent

discoveries of specific molecular events have added new levels of sophistication to tumor progression models, but the fact remains that there are multiple molecular paths to melanoma.

Signaling pathways

The signaling pathways can be separated into two main groups: those affected by germline mutations (Fig. 32.35A) and those affected by somatic mutations (Fig. 32.35B). The *CDKN2A*(p16)/CDK4/Rb pathway and BAP-1 are the main areas affected by germline mutations. Somatic mutations account for the vast majority of molecular defects in melanoma. Activation of signaling pathways, by direct stimulation, mutation, loss of inhibition, or other means, allows the cell to hijack its own regulatory machinery, leading to uninhibited growth. These pathways and corresponding mutations are global players in oncogenesis, observed in other tumor types, but are discussed here in the context of melanoma.

CDKN2A(p16)/CDK4/Rb pathway

CDKN2A (cyclin-dependent kinase N2A) is located on chromosome 9p21 and, by a splicing mechanism, encodes two distinct proteins: p16^{INK4a} and p14^{ARF}. *CDKN2A* is the main high-risk gene for familial melanoma.^{1443,1490} p16 is a well-studied tumor suppressor.^{1445,1491} p16 inhibits CDK4/6, which normally releases E2F from Rb by phosphorylation of Rb. The release of the transcription factor E2F transitions the cell from G₁ → S phase, initiating the cell cycle. An inactivated or absent p16 cannot block CDK4 and thus cannot put the brakes on cell division and proliferation. p14^{ARF} is also a well-known tumor suppressor that inhibits MDM2 (mouse double minute 2) from allowing the ubiquitination and thus degradation of p53.^{1446,1492} Because p53 is a tumor suppressor and a major player in apoptosis, a defective or absent p14 has the net effect of causing the rapid degradation of p53 and steering the cell away from apoptosis and cell death and toward survival. Although defects in *CDKN2A* are commonly associated with

Figure 32.35 Molecular pathways of melanoma. Alterations in the intracellular signaling pathways of the melanocyte can lead to an imbalance in proliferation/survival ↔ apoptosis/autophagy/cell cycle arrest signals, resulting in melanomagenesis. (A) The pathways that are more commonly altered in familial melanoma. White arrows are activation pathways. Blue lines are inhibition pathways. Dotted white lines correspond to indirect and/or less understood interactions.

Continued

Figure 32.35, cont'd Molecular pathways of melanoma. (B) The pathways that are more commonly altered in sporadic melanoma (B). White arrows are activation pathways. Blue lines are inhibition pathways. Dotted lines correspond to indirect and/or less understood interactions.

familial melanoma, somatic mutations (and somatic loss of 9p21) in sporadic melanomas are also quite common, supporting the important role of *CDKN2A* in melanomagenesis.^{1236,1486}

CDK4 (cyclin-dependent kinase 4) is located on chromosome 12q14 and encodes for the CDK4 protein. CDK4 is part of a network of cyclins and cyclin-dependent kinases involved in cell cycling. CDK4

specifically facilitates the $G_1 \rightarrow S$ transition, leading to cell division/proliferation. *CDK4* is an intermediary between p16 and Rb, and it activates Rb by phosphorylation.¹⁴⁹³ Defects in *CDK4* interfere with p16 binding, preventing inhibition by p16, and thus allowing uninhibited activation of Rb. *CDK4* mutations that prevent its binding to p16 have the same downstream effect as inactivating p16 mutations,

disrupting the normal 'brake system'. The most common *CDK4* mutations, R24C and R24H, are found at the p16 binding region of the protein.¹⁴⁴¹

BAP-1

BAP1 (BRCA1-associated protein-1) is a tumor suppressor gene located on chromosome 3p21 that encodes for the deubiquitinating enzyme ubiquitin carboxy-terminal hydrolase. *BAP1* is considered a high-risk gene for familial melanoma, and individuals who inherit an inactivated allele are at risk for uveal and cutaneous melanomas, among other tumors, in the context of the newly described *BAP1* hereditary cancer predisposition syndrome.¹⁴⁵⁷⁻¹⁴⁶¹ Typical of other tumor suppressor genes, the second allele is deactivated by some somatic genetic or epigenetic event, including, but not limited to, deletions, loss of heterozygosity, point mutations, and methylation.¹⁴⁹⁴ In addition to familial melanomas, *BAP1* mutations have been reported in 5 or 6% of sporadic cutaneous melanomas and atypical Spitzoid tumors.^{1495,1496} *BAP1*-inactivated melanocytic lesions often concurrently harbor the *BRAF* V600E mutation and not *HRAS* mutations.^{1495,1496} *BAP1* mutations in uveal and cutaneous melanomas are associated with a poor prognosis.^{1458,1496} *BAP-1* is known to interact with BRCA1, and its deubiquitinating activity and nuclear localization ability appear necessary for cell cycle control and apoptosis. It is also involved in histone modification and DNA repair, but its precise mechanism of action is currently unknown.^{1494,1497}

MC1R

MC1R (melanocortin-1 receptor) is located on chromosome 16q24 and encodes for a G protein-coupled receptor involved in melanin synthesis.¹⁴⁶³ Its ligand is α -MSH (melanocyte-stimulating hormone). Upon binding to MSH, *MC1R* activates CREB (cAMP response element binding protein), which upregulates MITF. The net effect is a swing from pheomelanin (red pigment) production to eumelanin (dark pigment) production. This process is mediated by tyrosinase and tyrosinase-related protein 1 (Tyrp-1), among other melanin-synthesizing enzymes. Eumelanin protects the skin from damage induced by UV exposure better than pheomelanin. Several *MC1R* genetic variants impact the eumelanin $\leftrightarrow$ pheomelanin balance. All the *MC1R* germline variants associated with an increased risk of melanoma are associated with *BRAF*-mutated tumors.¹⁴⁶⁷

MAP kinase (RAS/RAF/MEK/ERK) pathway

The MAP (mitogen-activated protein) kinase pathway is one of the main conduits for transmitting signals from the cell surface to the nucleus. Signaling through this pathway leads to activation of the cell, resulting in progression through the cell cycle and regulation of apoptosis and survival mechanisms. Cellular activation often begins with activation of upstream molecules (usually via cell surface receptors) followed by sequential activation of more downstream molecules, usually through phosphorylation. Signaling propagates in the following direction: Ras $\rightarrow$ Raf $\rightarrow$ MEK $\rightarrow$ ERK.¹⁴⁹⁸ Of course, the implied linearity of this pathway is an oversimplification. There are multiple members in each family of molecules, and there are elaborate checkpoints, compensatory pathways, and feedback mechanisms. More than 90% of melanomas have an activated MAP kinase pathway. Key components of this pathway are discussed.

Ras (Rat sarcoma) is a superfamily of G proteins, specifically small GTPases, and contains the most commonly mutated oncogenes in human cancer, found in up to one-third of human malignancies.¹⁴⁹⁹ There are three main gene members of its human subfamily: *NRAS*, *KRAS*, and *HRAS*. These encode GTPase N-Ras, K-Ras, and H-Ras, respectively. These Ras proteins localize to the plasma membrane and transmit signals from a cell surface receptor (receptor tyrosine kinase-like Kit) to downstream signaling pathways such as the MAP kinase and PI3K/Akt/mTOR pathways (see later). Activated Ras proteins activate Raf proteins (see later) in the MAP kinase pathway, mediated

by a process called farnesylation (which is a potential therapeutic target for cancers).¹⁵⁰⁰ The net effect of activated Ras is cell growth, division, and survival.

NRAS (neuroblastoma rat sarcoma viral oncogene homolog; 1p13.2) appears to be more important than *KRAS* and *HRAS* in melanomagenesis. Somatic *NRAS* mutations are observed in 15–20% of melanomas, compared with a combined 3% of melanomas harboring mutations in *KRAS* or *HRAS*.^{1441,1499,1501,1502} *NRAS* mutations are more commonly observed in certain subsets of melanoma, specifically nodular melanomas.^{1503,1504} *NRAS* mutations also are observed with variable frequency in superficial spreading melanomas,¹⁵⁰³ tumors from intermittently sun-damaged skin,¹⁵⁰³ and tumors from chronically sun-damaged skin.^{1503,1504} *NRAS* mutations are not common in acral and primary mucosal melanomas.^{1503,1504} *NRAS* mutations may predict a more aggressive biology, with reports of *NRAS*-mutated melanomas having a deeper tumor depth and higher mitotic rate at diagnosis, but these data are preliminary.¹⁵⁰⁵⁻¹⁵⁰⁷ *NRAS*-mutated tumors are not uniformly bad actors, and some appear to respond to high-dose interleukin-2 (IL-2).¹⁵⁰⁸ The most common *NRAS* mutations involve Q61, G12, and, less so, G13 residues.^{1509,1510} These mutations prevent GTP hydrolysis and lead to a constitutively activated N-Ras.¹⁵¹⁰ *NRAS* also is mutated in up to 40% of melanomas *in situ*, a subset of dysplastic (atypical) nevi, and up to 95% of giant congenital nevi.^{492,725,726,1511-1513} **HRAS** (v-Har-ras Harvey rat sarcoma viral oncogene homolog; 11p15.5) mutations are more often associated with Spitz nevi than with melanoma (*NRAS* and *BRAF* mutations are not typical).^{491,492} *HRAS* mutations and/or copy number changes of 11p (the site of the *HRAS* gene) are observed in 10–29% of Spitz nevi, and these lesions tend to have distinct morphologic features such as a large size and a sclerotic base.^{490,491} Germ-line *RAS* mutations do exist in the context of Noonan syndrome (*KRAS*, *NRAS*), Costello syndrome (*HRAS*), cardiofaciocutaneous syndrome (*KRAS*), and autoimmune lymphoproliferative syndrome 4 (*NRAS*), but germline *RAS* mutations are not associated with melanoma.¹⁵¹⁴

Raf (Rapidly accelerated fibrosarcoma) is a family of serine-threonine protein kinases. **BRAF** (v-raf murine sarcoma viral oncogene homolog B1), located on chromosome 7q34, is currently considered the most important Raf family member in melanomagenesis.¹⁵¹⁵ *BRAF* encodes serine-threonine protein kinase B-Raf (B-Raf). These B-Raf molecules reside in the cytoplasm as dimers and are recruited to the plasma membrane for activation by Ras. Once activated, B-Raf phosphorylates MEK (see later), continuing the MAP kinase cascade to cell proliferation and survival.

The *BRAF* gene is mutated in many cancers, including papillary thyroid carcinoma, colorectal carcinoma, ovarian carcinoma, lung carcinoma, hairy cell leukemia, and melanoma.¹⁵¹⁶ *BRAF* is one of the most commonly somatically mutated proto-oncogenes in melanoma, observed in approximately half of all melanomas.^{1509,1517-1519} In one of the first studies to screen melanoma patient samples ($n = 15$) and melanoma cell lines ($n = 34$), Davies *et al.* reported that the majority of activating *BRAF* mutations (>95%) occur at residue V600, with 95% of V600 mutations resulting in the specific valine to glutamic acid (V $\rightarrow$ E) substitution within the *BRAF* kinase domain.¹⁵¹⁷ In early studies, this was erroneously reported as V599E. Many subsequent studies have validated the high representation of B-Raf^{V600E} in melanoma, as well as reported other activating mutations at V600, such as V600K and V600R, and at other loci within the *BRAF* gene.^{1509,1520} The V600E mutation causes a conformational change to the catalytic domain, leading to constitutive activation with a several-log increase in activity of B-Raf and thus downstream activation of the MAP kinase pathway.^{1498,1521} The identical V600E mutation is seen in up to 82% of nevi (including common acquired, dysplastic, and small and medium congenital and congenital-like nevi), suggesting an early role for *BRAF* V600E in tumor progression.^{1522,1523} Germline *BRAF* mutations also occur, associated with the cardiofaciocutaneous syndrome, Noonan

syndrome, and LEOPARD syndrome, but not melanoma. These germline mutations are not the classic V600E mutations observed in cancer.^{1524,1525}

The mutations observed in *BRAF* for melanoma are not typical for UV-induced mutations, but there appears to be an association between *BRAF*-mutated melanomas and sun exposure. Curtin *et al.* reported that intermittent, not chronic, UV exposure is predictive of *BRAF*-mutated melanoma.¹⁵⁰³ The mutation is observed in 59% of melanomas from intermittently sun-exposed sites, whereas it is present in only 23% of acral melanomas, 11% of primary mucosal melanomas, and 11% of melanomas from chronically sun-damaged sites.¹⁵⁰³ These data are consistent with the fact that *BRAF*-mutated melanomas occur more frequently in younger individuals and in superficial spreading and nodular histologic subtypes (as opposed to older patients and the lentigo maligna subtype). *BRAF* mutations are unusual in desmoplastic melanoma.^{1526,1527} Other than histologic subtype, of which there is a loose association, there are no clear reproducible histologic features that predict *BRAF* mutational status.^{1528–1530} Several reports have suggested that *BRAF*-mutated melanomas have more aggressive features and worse patient outcomes,¹⁵¹⁹ but a clear association between *BRAF* mutational status and clinical outcome has yet to be established.^{1502,1528,1530,1531}

MEK and **ERK** are the downstream members of the MAP kinase pathway. MEK1/2 are two tyrosine–threonine kinases encoded by *MAP2K1* (15q22.1–q22.33) and *MAP2K2* (19p13.3). ERK1/2 are two serine–threonine kinases further downstream, encoded by *MAPK1* (22q11.2) and *MAPK3* (16p11.2). When MEK is phosphorylated by Raf, its catalytic activity is increased and, in turn, it phosphorylates ERK. ERK is the only known substrate of MEK. ERK is the most downstream of the phosphorylation proteins in this signaling cascade. When phosphorylated, it can directly activate transcription factors such as Myc, which can increase transcription of cell growth and survival genes within the nucleus. *MAP2K* (MEK) germline defects have been described in the cardiofaciocutaneous syndrome, but not melanoma. Somatic mutations in *MAP2K1* and *MAP2K2* (MEK) were reported in 8% of 127 metastatic melanoma samples in one study.¹⁵³² *MAPK1* and *MAPK3* (ERK) mutations do not appear to be common events.¹⁵⁰⁹ The prevalence and significance of primary activating mutations in MEK and ERK proteins for melanomagenesis remain unclear. However, because they reside downstream of Ras and Raf, these molecules are attractive as potential therapeutic targets.

KIT

KIT (v-kit Hardy–Zuckerman 4 feline sarcoma viral oncogene homolog; 4q11–q12) encodes mast/stem cell growth factor receptor Kit (also known as CD117). Kit is a member of a large family of tyrosine kinases, which also includes platelet-derived growth factor receptor (PDGFR), epidermal growth factor receptor (EGFR), hepatocyte growth factor receptor (HGFR or MET), and many more. When Kit binds its ligand, stem cell factor, it activates downstream molecules such as Ras and, by association, can activate the MAP kinase and PI3K/Akt/mTOR signaling pathways, among others. Kit plays a yet-to-be-fully characterized role in normal melanocyte migration and development.¹⁵³³ Amplifications and activating mutations have been described in leukemia, gastrointestinal stromal tumors (GISTs), seminomas, and melanomas, among others tumors. Similar to GISTs, the majority of *KIT* mutations in melanoma occur in the juxtamembrane domain (exon 11). This region is responsible for preventing activation of the kinase when Kit is not bound to its ligand. Mutations lead to constitutive activation. Functional mutations in other components of the molecule have been described.^{1498,1534,1535}

Kit overexpression is observed in approximately 3% of all melanomas. *KIT* mutations are uncommon in melanomas (usually the superficial spreading and nodular varieties) from intermittently sun-damaged skin. The importance of *KIT* in melanomagenesis is highlighted within

subsets of melanoma. Acral melanomas and primary mucosal melanomas account for only 5 and 2% of total melanomas in Caucasians, respectively. If melanomas are separated into subtypes, *KIT* amplifications and mutations are observed in 39% of primary mucosal melanomas, 36% of acral lentiginous melanomas, and 28% of melanomas on chronically sun-damaged skin.¹⁵³⁶ If only mutations, not amplifications, are considered (which may be a better gauge in terms of therapeutic response to Kit inhibition), these percentages are slightly lower (10–21%, 11–23%, and 17%, respectively).^{1534,1536,1537}

PI3K/Akt/mTOR/PTEN pathway

The PI3K/Akt/mTOR pathway is an activation pathway running parallel to the MAP kinase pathway. Similar to the MAP kinase pathway, the PI3K/Akt/mTOR pathway is an enzymatic cascade leading to cellular growth, proliferation, and survival, with main signal propagation as follows: PI3K → Akt → mTOR. PTEN is an inhibitor of this pathway at the point of PI3K. Most cancers, including up to 60% of melanomas, have alterations at some point within this pathway.¹⁵³⁸

PIK3CA (phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit α ; 3q26.3) encodes **PI3K**. PI3K can be activated by Ras, receptor tyrosine kinases, G protein-coupled receptors, or by other mechanisms. Activated PI3K subsequently activates Akt. Germline *PIK3CA* mutations can (rarely) result in Cowden syndrome and segmental overgrowth¹⁵³⁹ but not melanoma. Mutations and copy number changes of *PIK3CA* are common in many types of cancers, specifically breast and colon cancer. In melanoma, specific *PIK3CA* driving mutations occur in less than 3% of tumors, but activation of the PI3K/Akt/mTOR pathway (mainly by Akt activation or functional loss of PTEN)¹⁵⁴⁰ appears to be an important and common event.^{1536,1538}

Akt (v-akt murine thymoma viral oncogene homolog) is a family of serine–threonine kinases. Akt has three main family member genes: *AKT1* (14q32.32–q32.33), *AKT2* (19q13.1–q13.2), and *AKT3* (1q44). Akt is activated by PI3K, among others, and can activate a variety of substrates, including mTOR, bcl-2 family members, and NF- κ B. Germline *AKT1* mutations can (rarely) occur with Cowden syndrome but not melanoma. Akt is somatically activated in many human cancers, including melanoma, as well as Proteus syndrome.^{1538,1541} Approximately 1 and 3% of melanomas harbor a mutation at E17 in *AKT1* and *AKT3*, respectively.¹⁵⁴²

MTOR (mechanistic target of rapamycin; 1p36) encodes the serine–threonine protein kinase mTOR. mTOR interacts with other molecules forming complexes (mTORC1/mTORC2), which can feed back into the PI3K/Akt/mTOR pathway as well as activate more downstream molecules including mRNA translation regulators. The precise role of mTOR is unknown, but it appears to sense the nutritional status and oxidative stress level of the cell and control protein synthesis. It has a net effect of inhibiting autophagy. Specific driving mutations in *MTOR* are not widely found or well characterized, but because mTOR is activated with many cancers including melanoma, it is a potential therapeutic target.

PTEN (phosphatase and tensin homolog; 10q23.31) is a tumor suppressor gene encoding PTEN, an inhibitor of cell division and promoter of apoptosis. PTEN blocks PI3K and thus negatively regulates the PI3K/Akt/mTOR pathway. Therefore, *PTEN* inactivation leads to activation of the PI3K/Akt/mTOR signaling pathway and thus cell growth and survival. Inactivation of *PTEN* can be achieved by a variety of mechanisms, including missense mutations, frameshifts, deletions, insertions, loss of heterozygosity, and epigenetic silencing.^{1540,1543} Germline defects in *PTEN* are observed in the *PTEN* hamartomatous syndromes (Cowden, Bannayan–Riley–Ruvalcaba, and Lhermitte–Duclos) and Proteus-like syndrome, but not melanoma. *PTEN* is inactivated somatically or has reduced expression in many human cancers, including 10–30% of melanomas.^{1540,1543} In melanoma pathogenesis, *PTEN* mutations are thought to be important when present in conjunction with activating mutations in other pathways, such as *BRAF* in the MAP

kinase pathway. *NRAS* and *PTEN* mutations rarely occur in the same tumor.¹⁵⁴⁴ Loss of *PTEN* protein expression is observed in 8% of nevi, suggesting a possible role for *PTEN* in tumor progression.¹⁵⁴⁵

GNAQ/GNA11

GNAQ (9q21) and its family member *GNA11* (19p13.3) encode for the α subunit of the heterotrimeric G protein complex. These proteins are designated guanine nucleotide binding protein G(q) subunit α and guanine nucleotide binding protein subunit α -11 (referred to as *GNAQ* and *GNA11*, respectively). This G protein complex is required to transmit signals from transmembrane G protein-coupled receptors to internal signaling pathways, such as the MAP kinase and PI3K/Akt/mTOR pathways, mediated by activation of phospholipase C. Mutational hot spots in *GNAQ* and *GNA11* include Q209 and R183, resulting in constitutive activation of the G protein complex and subsequent downstream signaling.¹⁵⁴⁶ *GNAQ* and *GNA11* mutations (either but not both) are fairly common in a narrow range of lesions, including up to 80% of uveal melanomas and most blue nevi, but not cutaneous melanoma.^{870,1547} In one study, *GNAQ* mutations were present in 45% of uveal melanomas and 55% of blue nevi, whereas *GNA11* mutations were present in 32% of uveal melanomas and 7% of blue nevi.¹⁵⁴⁷

Other mechanisms

Although the previously discussed pathways appear to be the most common and important for melanomagenesis, this is not a comprehensive list. *TERT* (telomerase reverse transcriptase; 5p15) encodes for the catalytic reverse transcriptase subunit of the telomerase complex. Telomerases lengthen telomeres, a well-known mechanism in oncogenesis.^{1548–1550} Recently, recurrent mutations in the *TERT* promoter region, specifically C228T and C250T, were discovered by

analyzing noncoding regions of whole-genome data.¹⁵⁵¹ These mutations were identified in 24/150 (16%) diverse cell-type cancer cell lines and 50/70 (71%) melanomas. A separate study found *TERT* promoter mutations in 25/77 (33%) of paraffin-embedded primary melanomas.¹⁴⁷¹ To date, the four most common nucleotide substitutions observed in melanoma are *BRAF* bp1799A>T (V600E), *NRAS* bp182T>C (Q61R), *TERT* C228T, and *TERT* C250T.¹⁵⁵¹ *TERT* promoter mutations likely play a role in the reactivation of telomerases, and in the setting of other oncogenic driving mutations, they lead to melanocyte immortality. **Microsatellite instability** occurs in a considerable subset of patients with melanoma and is also observed in nevi.^{1552–1556} It is more common in pediatric than adult melanomas.¹⁵⁵⁷ The role of **autophagy** pathways in melanoma is an emerging area of interest.^{1558–1561}

Tumor progression

With a new wealth of understanding of the many genetic events observed in melanoma, investigators can focus efforts on characterizing the precise mechanisms of action and chronology of such events. Tumor progression models have been proposed,^{963,1562,1563} but these are not as well characterized as models for other tumors, such as colorectal cancer.¹⁵⁶⁴ Most melanoma models include progression from a normal melanocyte to metastatic melanoma, with variations of the following theme: **melanocyte** → **nevus** → **dysplastic (atypical) nevus** → **melanoma in situ** → **invasive melanoma** → **metastasis** (Fig. 32.36). This progression occurs with an accumulation of somatic mutations and epigenetic events, possibly mediated, in part, by UV radiation due to its mutagenic effects on DNA. These models remain controversial due to an abundance of ‘molecular gaps’, clear examples of tumors skipping steps, and poorly histologically defined steps (atypical/dysplastic nevi), among others. Nonetheless, development of tumor

Figure 32.36 A tumor progression model for melanoma. Possible roles for environmental, genetic, and epigenetic events in the progression from a normal melanocyte to invasive melanoma are shown. Amplifications of genes, such as *CCND1* and *CDK4*, are also important in tumor progression (not shown). Progression models are controversial because melanoma is genetically heterogeneous, not all tumors progress through every depicted stage, and steps are ill-defined. The positions of genes in the model are theoretical. Similar models have been proposed for melanoma and other tumors.^{1018,1562,1564} *Primarily observed in uveal and blue nevus-like melanomas.

progression models remains important for understanding the molecular players in the growth/survival $\leftrightarrow$ arrest/death balance of the cell and points of potential therapeutic intervention.

Within the melanoma tumor progression models, the *BRAF* mutation is considered to be an early event.²¹¹ This is supported by the finding that the identical V600E mutation in melanoma is also observed in up to 82% of nevi, and there is molecular evidence for clonality in nevi.^{1522,1523,1565} Not all nevi become melanoma, however. Only one-fourth to one-third of melanomas are estimated to arise from or at the site of a nevus.^{1115,1348} B-Raf^{V600E} results in constitutive activation of the MAP kinase pathway, but it appears that, at least in some scenarios, isolated *BRAF* mutations induce senescence, possibly after a finite number of cell divisions, to create a nevus and not melanoma.¹⁵⁶⁶ This concept has been termed oncogene-induced senescence.^{299,1567} *BRAF* mutations may require another molecular 'hit' in an alternative signaling pathway, such as the PI3K/Akt/mTOR pathway, to transform. Otherwise, the cell undergoes oncogene-induced senescence.^{1529,1568} Although *BRAF* and *NRAS* mutations are common in melanoma (40% of *in situ* tumors and 81% of invasive melanomas), mutations in both genes in the same tumor are rarely observed because their mutations appear largely mutually exclusive. Mutual exclusivity is typical for proto-oncogenes in the same signaling pathway. *NRAS* mutations may be more powerful oncogenic drivers than *BRAF* mutations because N-Ras is upstream and can activate both MAP kinase and PI3K/AKT/mTOR pathways, effectively causing a 'two-for-one hit'. The precise role of *TERT* in melanomagenesis is unclear but intriguing because *TERT* is involved in a completely different mechanism of survival – reactivation of telomerase. *TERT* promoter mutations are presumed to be relatively early molecular events in melanomagenesis due to their prevalence, but they are found more commonly in metastases than in primary tumors and are rarely found in nevi.^{1471,1551} Like *BRAF* mutations, *TERT* mutations likely require additional oncogenic driving mutations in other pathways to overcome oncogene-induced senescence.^{1471,1551} Other genes, such as *KIT*, may play an early role in tumor progression, especially with certain melanoma subtypes (lentigo maligna, acral lentiginous, and primary mucosal). The PI3K/Akt/PTEN pathway genes likely are important in the intermediate stages of progression, and *VEGFA* (vascular endothelial growth factor A), *TP53* (p53), *CDH1* (E-cadherin), and others are likely involved in invasion and metastasis.^{1569–1573}

Although a stepwise progression predicted by the model may occur in some tumors, it is clear that melanocytes can find many different molecular paths to melanoma. Furthermore, melanoma has a fairly unique and stubborn ability to arrest its progression in its later stages, in some cases with ultra-late recurrences more than four decades post diagnosis.^{1574,1575} The exact roles of these signaling molecules and their mutational or epigenetic events in the progression from normal melanocyte to metastatic melanoma continue to be investigated.

Classification of melanoma

The clinicopathological classification of melanoma has evolved into six groups, based on proposals by Clark *et al.*¹⁵⁷⁶ and McGovern *et al.*¹⁵⁷⁷ more than 40 years ago. The relative incidence of each type of melanoma varies considerably in different geographical areas. For example, there is a higher proportion of lentigo maligna melanomas in white populations living in subtropical and tropical areas¹⁵⁷⁸ and of acral lentiginous melanomas in Japanese¹¹⁸⁸ and African/African American populations.¹⁵⁷⁹ In addition, age and type of UV exposure impact relative incidence, with lentigo maligna melanoma occurring with much higher frequency in elderly populations and those with extensive chronic sun damage.^{1181,1580} The percentages in parentheses are therefore only a guide to the relative incidence of each type:

- Lentigo maligna melanoma (10–40%)
- Superficial spreading melanoma (30–60%)¹⁵⁸¹

- Nodular melanoma (15–35%)
- Acral lentiginous melanoma (5–10%)
- Desmoplastic melanoma (rare)¹⁵⁸²
- Miscellaneous (rare).

Desmoplastic melanomas are distinctive lesions. In their pure form (see p. 881), some authors consider them to be more akin to sarcoma than melanoma, in terms of biologic behavior. Moreover, the immunohistochemical and electron microscopic characteristics (see p. 882, 890) provide only modest evidence for a melanocytic origin, although a melanocytic origin is generally accepted. This entity is at high risk for future reclassification.

Included in the miscellaneous group are melanomas arising in blue nevi, Spitzoid melanomas, primary dermal melanomas,^{1583–1585} and *BAP1*-mutated melanomas.^{1457,1461} Amelanotic melanoma is best regarded as a poorly differentiated melanoma, usually of nodular type, rather than a distinct subtype.^{1586,1587} Other rare histological variants, such as the signet-ring cell melanoma, the balloon cell melanoma, the small cell melanoma, the nevoid melanoma, and the myxoid melanoma, can be included in the miscellaneous group. These histological variants are discussed further on page 884 and page 898 (for *BAP1*-inactivated tumors).

Ackerman long questioned the validity of this traditional classification of melanomas.¹⁵⁸⁸ After all, conventional treatment strategies have been independent of histologic subtype. He stated in support of his 'unifying concept' of melanoma that no list of repeatable and reliable criteria for differentiation of the reputed types of melanoma has been published.¹⁵⁸⁸ This statement has been supported by some but questioned by others.^{1589–1591} The emergence of molecular data has put this debate to rest.

It is now clear that melanoma is not one disease but, rather, a complex molecularly heterogeneous array of different tumor types. As the molecular signaling pathways are uncovered further, melanoma likely will be better classified based on its mutational profile and predicted response to therapy. Proposals to reclassify melanoma based on molecular profile and degree of UV exposure have already begun. Using array comparative genomic hybridization (aCGH) techniques, Curtin *et al.* analyzed DNA copy alterations and mutational status of *BRAF* and *NRAS* on 126 melanomas divided into four categories based on UV exposure: tumors from chronically sun-damaged skin, skin without chronic sun damage, acral sites, and mucosal sites.¹⁵⁰³ In this study, the mutational status of *BRAF* and the DNA copy number of certain loci (specifically *CDK4* and *CCND1*) could accurately classify the tumor into one of the four categories. Furthermore, 81% of tumors from skin without chronic sun damage had mutations in *NRAS* or *BRAF*, whereas this was uncommon in the other categories. A follow-up study analyzed 102 melanomas by aCGH to specifically search for DNA copy number changes and candidate oncogenes in the tumors with wild-type *BRAF* and *NRAS*.¹⁵³⁶ In this study, *KIT* mutations and/or copy number changes were identified in 39% of mucosal melanomas, 36% of acral melanomas, 28% of melanomas on chronically sun-damaged skin, and 0% in skin without sun damage.^{1181,1503,1536} Subsequent studies have expanded on this idea with the following conclusions: (1) *BRAF* mutations are frequent in superficial spreading melanoma (and melanomas from intermittently sun-damaged skin), whereas *NRAS* mutations are frequent in nodular melanomas (and, reported by Lee *et al.* in a meta-analysis, melanomas from chronically sun-damaged skin),¹⁵⁰⁴ and (2) *BRAF* mutations occur at low frequency, whereas *NRAS* and *KIT* mutations are not present in spindle cell (including desmoplastic) melanomas.^{1526,1527} Based on these studies and more, conventional classifications likely will evolve into newer systems that incorporate anatomic site, type/duration of UV exposure and degree of sun damage, histomorphology, and the mutational status of *BRAF*, *NRAS*, and *KIT*, among others. An integrated taxonomy of melanocytic lesions has recently been proposed by Bastian.¹⁵⁶³ For now,

however, the conventional histomorphologic classification of melanoma remains the standard.

Clinical features¹⁵⁹²

Although there is some validity in Ackerman's contention that a clinical distinction cannot always be made between the various types of melanoma that have traditionally been recognized,¹⁵⁹² a clinical description of each of these generally accepted types is given here.¹⁵⁹³ First, however, there are several unrelated clinical aspects of melanoma that should be mentioned: the rarity of melanomas in childhood,^{1594–1599} the very rare occurrence of congenital melanomas,^{727,728,1600–1602} and the development in some patients of a paraneoplastic syndrome.¹⁶⁰³ Melanoma-associated retinopathy is one such paraneoplastic phenomenon.^{1604,1605} Some of the melanomas in children and in adolescents arise in small congenital nevi;^{1595,1606} others arise *de novo*. The natural history of melanomas in children appears to be similar to that in adults,^{1607–1610} although the survival advantage for adult females is not seen in children.¹⁶¹¹ Furthermore, the prognosis for congenital and infantile melanomas is poor.¹⁶¹² Diagnosis is sometimes difficult, both clinically and histopathologically,^{539,1613,1614} sometimes leading to delayed diagnosis and the removal of thicker lesions.^{1615–1618}

The distribution of melanomas is related to their type (see later). Overall, the back is the most common site for melanomas in males and the lower extremities in females.¹⁶¹⁹ There is a left-sided excess of approximately 15% in the laterality of cutaneous melanoma.¹⁶²⁰

Attempts have been made to characterize the clinical features of melanoma in an easily remembered mnemonic. The ABCD rule highlights the clinical characteristics: *asymmetry*, *border irregularity*, *color variegation*, and *diameter greater than 6 mm*.^{1621–1623} Subsequently, the importance of changes in shape, size, symptoms (e.g., itching and tenderness), surface, and shades of color of a pigmented lesion was recognized by adding an E (for *evolution* or *enlarging*) to the ABCD acronym.^{1624–1626} Correspondence resulting from this change to the acronym suggested that adding letters to the acronym may not be the best approach.^{1627–1629} Change in a lesion was regarded as an important sign.¹⁶²⁹ It has also been suggested that 'D' should represent dark color and not diameter because melanomas less than 4 mm in diameter are not infrequent.¹⁶³⁰ Fake tan may be a cause of a change in color of a pigmented lesion.¹⁶³¹ Based on these criteria, Ackerman concluded from photographs that Franklin D. Roosevelt, a former President of the United States, had a melanoma above his left eyebrow.¹⁶³² Many exceptions to the ABCD rule occur,^{1633–1635} leading to clinical misdiagnoses.^{1636–1640} Laypersons are capable of applying the ABCD criteria when it is explained to them.¹⁶⁴¹ The 'ugly duckling' sign has a reasonable degree of specificity in diagnosing melanomas.^{1642,1643} This sign refers to a lesion that is different from other moles on the patient.¹⁶⁴² These various signs appear to be usable by both dermatologists and primary care physicians to diagnose melanomas.^{1644,1645} In one systematic review, the sensitivity for diagnostic accuracy among dermatologists was 0.81–1.00 and for primary care physicians it was 0.42–1.00.¹⁶⁴⁶ Despite these results, seborrheic keratoses that mimic melanoma clinically continue to be seen.¹⁶⁴⁷ Melanomas are frequently asymptomatic.¹⁶⁴⁸ They may also have hairs protruding from them.¹⁶⁴⁹

Lentigo maligna melanoma occurs most frequently on the face and sun-exposed upper extremities of elderly people.¹⁶⁵⁰ Its precursor lesion, the lentigo maligna (Hutchinson's melanotic freckle), is an irregularly pigmented macule that expands slowly. There is great variation in color, with tan-brown, black, and even pink areas present. Perioral lesions rarely spread onto oral mucosa.¹⁶⁵¹ An amelanotic variant has been reported;^{1652–1658} rarely, this takes the form of an inflammatory plaque¹⁶⁵⁹ or follows cryosurgery or other therapy for lentigo maligna.^{1660,1661} Invasive malignancy (vertical growth phase) is characterized by thickening of the lesion with the development of elevated plaques or discrete nodules. The proportion of lentigo

malignas that progress to lentigo maligna melanoma is said to be quite small, with a lifetime risk of only approximately 5%.¹⁶⁶² Rapid progression to a deeply invasive tumor has been reported.^{1655,1663} A contiguous solar lentigo is present in 30% of lentigo malignas and a pigmented actinic keratosis in 24%.¹⁶⁶⁴ The latter lesion is frequently confused with melanoma on dermoscopy. In other parts of the solar lentigo, evolution into a seborrheic keratosis may also occur.

A recent study showed that the *BRAF* V600K mutation is more frequent than the *BRAF* V600E mutation in melanoma *in situ*, lentigo maligna type. This mutation was found exclusively in DNA from the tumor area and not in DNA from surrounding tissue. However, the overall mutation frequency seen in samples from lentigo maligna tissues was relatively low, with only 21% of the samples harboring V600 mutations in the *BRAF* gene.¹⁶⁶⁵

Cryotherapy, topical imiquimod,^{1666–1674} imiquimod with cryotherapy,¹⁶⁷⁵ radiotherapy,¹⁶⁷⁶ surgical excision with mapping^{1677,1678} or peripheral vertical ± horizontal sections for margin control,^{1679–1682} and a modified Mohs micrographic technique, using immunoperoxidase staining with HMB-45 or MART-1, have all been proposed as suitable methods of treatment for lentigo maligna.^{1683–1691} Dermoscopy and confocal microscopy have been used to better define the edge of a lentigo maligna prior to surgery.^{1692,1693} Staged excision can also be used.^{1694,1695} Clinical margins of 5 or 6 mm result in inadequate excisions in approximately 15% of patients.¹⁶⁹⁶ Unfortunately, cryotherapy may be followed by lentiginous hyperpigmentation in the scar, which requires differentiation from a recurrence.¹⁶⁹⁷ Topical 1% cidofovir was used successfully in two cases involving the cheek in elderly patients.¹⁶⁹⁸ The use of treatment modalities other than surgical excision for melanoma *in situ* carries a significantly increased risk of local recurrence.^{1699,1700} There is no consensus, at least in the United States, as to what surgical margins should be in cases of melanoma *in situ* (see p. 895).¹⁷⁰¹

The **superficial spreading melanoma** may develop on any part of the body and at any age.¹⁷⁰² It is particularly common on the trunk in males and the lower extremities in females. The umbilicus is a rare site.¹⁷⁰³ It has a shorter radial growth phase than lentigo maligna melanoma. It also has a variegated color with an irregular expanding margin. An amelanotic variant has also been reported,¹⁷⁰⁴ rarely, it may clinically simulate a patch of vitiligo.¹⁷⁰⁵ Areas of regression are not uncommon in both this type of melanoma and the lentigo maligna form. In a population-based case-control study from Queensland, Australia, it was found that a high nevus propensity was a stronger predictor of superficial spreading melanoma, whereas a propensity to lentigines was a stronger predictor of lentigo maligna melanoma. In addition, skin cancer history was determinative of lentigo maligna melanoma, whereas the number of lifetime sunburns determined superficial spreading melanoma.¹⁷⁰⁶ Differences between superficial spreading and nodular melanoma include the following: (1) *BRAF* mutation is less common in nodular melanoma than in superficial spreading melanoma; (2) genomic analysis shows a 'dip' in gene expression levels in superficial spreading melanoma compared to nevi and nodular melanoma that does not fit the stepwise transformation model sometimes proposed for these lesions (see section on tumor progression, p. 875), suggesting that they are separate biologic entities; (3) the majority of microRNAs are downregulated in superficial spreading melanomas compared to congenital nevi and nodular melanomas; and (4) there are differences in nestin expression (reduced in superficial spreading melanomas) and levels of the cryptic epitope HU177, which plays a role in angiogenesis and tumor growth (higher levels in nodular melanoma).¹⁷⁰⁷

Nodular melanomas have no antecedent radial growth phase. They are therefore nodular, polypoid,^{1708,1709} or occasionally pedunculated,¹⁷¹⁰ dark brown or blue-black lesions occurring anywhere on the body. Occasionally, flesh-colored amelanotic variants are found.^{1711,1712} They often fail to fulfill the ABCD diagnostic criteria.¹⁷¹³ Ulceration may be present. A giant lesion, 12 cm in width, has been reported.¹⁷¹⁴

Acral lentiginous melanomas¹⁷¹⁵ develop on palmar, plantar, and subungual skin.^{1716–1724} They are particularly common in black people and the Japanese^{1725–1729} and Taiwanese,¹⁷³⁰ and they are found predominantly in elderly patients, with a male preponderance. They account for more than half the melanomas in Chinese people.¹⁷³¹ They present as pigmented plaques or nodules that are often ulcerated. In one series, 37% were subungual and the remainder were on the soles, palms, and nonvolar sites.¹⁷³² Subungual melanomas may present as longitudinal melanonychia.¹⁷³³ They may evolve slowly.¹⁷³⁴ Atypical presentations such as intertriginous ulcerated areas and amelanotic variants have been reported.^{347,1735–1737} They are frequently misdiagnosed as benign disease.^{1738–1741} Disease is often advanced at the time of diagnosis.¹⁷³² Not all melanomas on volar and subungual skin are of acral lentiginous type, with some being of superficial spreading, nodular, or unclassifiable type.^{1742–1746} In one series of subungual melanomas, only half were of acral lentiginous type.¹⁷⁴⁷ In the series of 124 subungual cases from the Sydney Melanoma Unit, 66% were of the acral lentiginous type, 25% were of nodular type, and 7% were desmoplastic.¹⁷⁴⁸ The most common site of the lesions in this series was the great toe.¹⁷⁴⁸ Subungual melanoma *in situ* has been reported in a child.¹⁷⁴⁹ It has also developed simultaneously on both thumbs.¹⁷⁵⁰ It may present as longitudinal melanonychia.¹⁷⁵¹ The finding of a parallel ridge pattern on dermoscopy may aid the diagnosis of early lesions of acral melanoma *in situ*.¹⁷⁵² Alterations in RAS pathways are present in more than 87% of acral lentiginous melanomas.¹⁷⁵³

Melanomas of the oral cavity and other mucous surfaces, such as the vagina, have been included in this group by some but excluded by others.^{1743,1754,1755} There are some clinical and histological similarities between mucosal melanomas and those of volar skin.^{1756,1757} The term ‘**mucosal (lentiginous) melanomas**’ is sometimes used. Mucosal melanoma remains a rare disease, accounting for 0.03% of all new cancer diagnoses.¹⁷⁵⁸ Oral melanomas are a rare subset of mucosal melanomas.¹⁷⁵⁹ In a large Swedish series of 219 cases of melanoma of the vulva, the vast majority were of the mucosal (acral) lentiginous type.¹⁷⁶⁰ The prognosis of vulvar melanomas (37–47% 5-year survival) is poorer than for other cutaneous melanomas.^{1761,1762} They tend to be thicker lesions and to occur in older women.^{1763,1764} The mean Breslow thickness in one series was 2.8 mm.¹⁷⁶⁵ Approximately 500 cases of vulvar melanoma have been reported.¹⁷⁵⁸ It has developed in patients with lichen sclerosis.¹⁴³¹ Vaginal melanomas are quite rare.¹⁷⁶⁶

Desmoplastic melanoma is usually found on the head and neck region as a spreading indurated plaque or bulky, firm tumefaction.^{1767–1774} There is a male predominance in many series¹⁷⁷⁵ but not all.¹⁷⁷⁶ Atypical presentations occur.^{1777,1778} Desmoplastic melanoma of the lip is not uncommon in young people.¹⁷⁷⁹ Alopecia neoplastica is a very rare presentation.¹⁷⁸⁰ The lesions are often nonpigmented, although focal pigmentation may be observed.¹⁷⁸¹ Desmoplastic melanomas are often stubbornly recurrent;¹⁷⁶⁷ in many instances, this is a reflection of inadequate surgical excision of a lesion that is often, locally, quite advanced in its growth.^{1770,1782} In one study of 33 patients, 4 (12%) had at least one positive sentinel lymph node.¹⁷⁸³ In one series, the 5-year disease-free survival rate was 68%.¹⁷⁸⁴ In another series, desmoplastic melanomas with neurotropism had a significant decrease in survival.¹⁷⁸⁵ Neurotropic melanomas may invade cranial nerves and their major branches.¹⁷⁸⁶ In a large series reported from the Sydney Melanoma Unit, the 5-year survival was 75%, which was similar to that for patients with other cutaneous melanomas of similar thickness.¹⁷⁸⁷ In another study of 113 cases published in 2008, approximately 4% had local recurrences, 2% had lymph node invasion, 9% had systemic metastases, and 12% had died from the disease.¹⁷⁷⁶ The dermoscopy of desmoplastic melanomas is difficult. In the absence of a pigmented network, attention should be given to the identification of features of regression and to melanoma-associated vascular patterns.¹⁷⁸⁸

Wide surgical excision without adjuvant radiotherapy has been recommended for desmoplastic melanomas.¹⁷⁸⁹ A 3-cm clearance was

previously recommended, although this is not usually achievable on parts of the face. A 2-cm clearance has been suggested.¹⁷⁸⁹ The clearance given is a surgical clearance, not a histopathological one.¹⁷⁸⁹ Local recurrence is more likely in the presence of neurotropism in the original lesion.¹⁷⁸⁹ ‘Pure’ desmoplastic melanomas uncommonly metastasize to regional lymph nodes, and some believe that sentinel node biopsy is not warranted in this group.¹⁷⁹⁰ They are associated with longer disease-free survivals than the ‘mixed’ group (see later).¹⁷⁹¹

Histopathology

Before considering the histopathological features of each subtype of melanoma, three aspects require consideration:

- The concept of radial and vertical growth phase
- The nomenclature for precursor lesions, including the radial growth phase
- The examination and reporting of melanomas.

Clark and colleagues introduced the concept of radial and vertical growth phases in the evolution of a malignant melanoma.¹⁷⁹² Note that this concept is in flux as new molecular data emerge. The radial growth phase refers to the progressive centrifugal spread of a flat pigmented area, which is characterized by intraepidermal proliferation of atypical melanocytes with features that differ in lentigo maligna, superficial spreading melanoma, and acral lentiginous melanoma. The net growth of such a lesion is therefore in a horizontal, or radial, dimension. It is generally agreed that multiple melanocytes (a ‘field’), rather than a single melanocyte, are responsible for the beginning of a melanoma.^{1793,1794}

The radial growth phase precedes the development of the vertical growth phase, although nodular melanomas have no radial growth. Invasion of the papillary dermis does not have the same prognostic connotations as penetration of the reticular dermis; the concept of radial growth has therefore been defined to include lesions with invasion of the papillary dermis by cells, either single or in small nests, resembling those in the epidermis,^{1792,1795} as long as the net growth is radial as determined by histopathologic evaluation. The presence of dermal mitoses excludes this diagnosis. Melanomas in this phase may be incapable of metastasis.¹⁷⁹⁶ A vertical growth phase lesion is one in which the net growth is in a vertical direction through the dermis. This is most easily demonstrated by a primary melanoma with a nodular, expansile dermal component. Lesions that fill the papillary dermis in this manner – the classic Clark’s level III (or higher) lesion – are said to be in vertical growth phase. However, also included within the definition of vertical growth phase lesions are those that demonstrate ‘accretive’ growth within the dermis (in which smaller nests are seen to aggregate within the dermis), those with intradermal nests that are larger than any junctional nest, and those with dermal mitotic activity.¹⁷⁹⁷ Angiogenesis and expression of vascular endothelial growth factor are associated with the development of the vertical growth phase and tumor progression.^{1798,1799} Other mechanisms are also involved, but they are complex and poorly understood.^{1800–1806} Destruction or loss of the basement membrane is not mandatory for melanoma invasion.¹⁸⁰⁷ Vertical growth phase is an adverse prognostic factor for cutaneous melanoma.¹⁸⁰⁸

There is considerable controversy regarding the nomenclature to be used for presumed precursor lesions of malignant melanoma.^{1809–1816} Terms such as ‘atypical melanocytic hyperplasia’, ‘pagetoid melanocytic proliferation’, ‘pagetoid melanocytosis’, ‘precancerous melanosis’, ‘severe melanocytic dysplasia’, and, more recently, ‘dysplastic (atypical) nevus’ have been used for these precursor lesions, and not always consistently.^{1817–1819} Some have used the term ‘melanoma *in situ*’ for evolving melanocytic atypias,^{1818,1820} whereas others have avoided the term because of the connotation for insurance purposes of the word ‘melanoma’ in this title. This latter practice has been criticized.^{1821,1822} The Consensus Conference on the early diagnosis and treatment of melanomas, convened by the National Institutes of

Health (USA), agreed that ‘melanoma *in situ*’ is a distinct entity.¹⁸²³ In the most recent World Health Organization publication, lentigo maligna is regarded as a type of melanoma *in situ*.¹⁸²⁴ These latter concepts have been criticized by Ackerman and others.^{1650,1825–1827} To overcome this controversy, it has been suggested that the term ‘melanocytic intraepidermal neoplasia (MIN)’ be applied to these lesions in the same way that cervical intraepithelial neoplasia (CIN) is used for the cervix.^{1828,1829} This term is little used outside the United Kingdom.

Despite the above, the epidermal component (radial growth phase) of melanomas of the lentigo maligna, superficial spreading, and acral lentiginous types is usually histologically distinctive.^{1830,1831} It may be difficult to assign a classification in approximately 5% of melanomas because of overlap features. Precursors to forms of melanoma *in situ* remain difficult to characterize histologically.

The pathology report for a primary melanoma should provide, at minimum, all of the available histologic data required for optimal patient management. The most important data are those that impact staging (see p. 892). Therefore, at a minimum, Breslow depth ± ulceration, mitotic count, and comments on in-transit/microsatellite lesions should be included. Many other histologic features often are included for completeness and/or data-mining purposes. The College of American Pathologists (CAP) regularly updates synoptic reporting templates with online access.¹⁸³² Synoptic reporting has been advocated for standardization.¹⁸³³ Suboptimal reporting and lack of compliance with reporting protocols have been documented previously in the United Kingdom and the United States.^{1834,1835} Clark’s levels were previously used to assess tumor depth in cutaneous lesions; they have been supplanted by Breslow depth measurements and are no longer required for reporting in accord with current American Joint Committee on Cancer (AJCC) staging criteria. However, they are still reported in some institutions and can be helpful in particular circumstances. For example, for lesions of comparable thickness, a Clark’s level IV lesion (involving the reticular dermis) may have a worse prognosis than a Clark’s level III lesion (filling, but still confined to, the papillary dermis).

There is a disappointing degree of disagreement between experts in the diagnosis of melanocytic neoplasms.^{594,1836–1843} Nevertheless, expert review of problematic cases improves patient care.¹⁸⁴⁴ Errors in diagnosis, leading to litigation, are not uncommon.^{1845–1847} Nevertheless, it is generally agreed that in a very small number of cases the diagnosis is elusive and that expressing diagnostic uncertainty is acceptable.¹⁸⁴⁸ Also note that incisional biopsies with ≥50% of the clinical lesion remaining after biopsy may be inadequate for accurate microstaging of the melanoma, leading to upstaging of approximately 20% of cases on their complete removal.¹⁸⁴⁹ Scolyer *et al.* cautioned that any incomplete biopsy (shave or punch) of melanocytic lesions can impair the accuracy of the pathological diagnosis.¹⁸⁵⁰

Criteria for the diagnosis of malignant melanoma¹⁸⁵¹ are listed in Table 32.4.

Lentigo maligna melanoma has a precursor (*in situ*) component, termed **lentigo maligna**, characterized by atypical melanocytes, singly and in nests, usually confined to the basal layer and with little pagetoid invasion of the epidermis (Fig. 32.37).^{1850,1852,1853} No consistent criteria have been proposed for distinguishing lentigo maligna from precursor lesions, although the presence of junctional nesting, deep adnexal involvement, melanocyte crowding with confluence, atypia, and the presence of melanocytes above the basal layer have been used as markers of melanoma *in situ*.^{1854,1855} If nesting is more than focal, the term ‘nevroid lentigo maligna’ may be used. Such cases can be misinterpreted as dysplastic nevi on partial biopsies of the lesions.¹⁸⁵⁶ There is often some epidermal atrophy. Multinucleate melanocytes with prominent dendritic processes (the ‘starburst giant cell’) are often present in the basal layer.^{1857,1858} The invasive component usually is composed of spindled melanocytes, but epithelioid melanocytes may be observed. There is variable cytological atypia. In some cases, there

Table 32.4 Histological criteria for the diagnosis of malignant melanoma

Architectural criteria
Asymmetry
Poor circumscription
Consumption of the epidermis
Epidermal nests of melanocytes showing:
• Confluence
• Variability in size and shape
• Haphazard interval and array
Solitary epidermal melanocytes showing:
• Predominance over nests
• Pagetoid spread
• Haphazard arrangement
Dermal nests showing:
• Variability in size and shape
• Confluence
• Lack of maturation in depth
• Variability in melanin distribution
Melanocytes within lymphovascular spaces
Cytological criteria

Figure 32.37 Lentigo maligna. There are atypical melanocytes in the basal layer of the epidermis. Elastotic changes are present in the dermis. (H&E)

are plentiful mitoses, with considerable nuclear pleomorphism and even tumor giant cells. The upper dermis usually shows moderate to severe solar elastosis and the presence of pigment-containing macrophages and small collections of lymphocytes. Sometimes there is downward displacement of the solar elastosis by tumor nests.¹⁸⁵⁹ However, solar elastosis is not a prerequisite for the diagnosis.¹⁵⁹⁰ Melanomas with solar elastosis tend to occur at an older age.¹⁸⁶⁰ Immunohistochemistry may be helpful for evaluating microinvasion in lentigo maligna melanoma¹⁸⁶¹ and in other settings (see p. 889).

It is a well-recognized phenomenon that a subsequent excision may show more pronounced (atypical) features than a previous biopsy specimen. This is particularly so for lesions on actinically damaged

skin, in which up to 40% of excisions may show more pronounced changes.^{1862,1863}

Dermoscopic features of lentigo maligna/lentigo maligna melanoma include asymmetrical pigmented follicular openings, rhomboidal structures, annular-granular structures, and a gray pseudo-network.¹⁰² In contrast, solar lentigines show comedo-like openings, diffuse opaque brown pigmentation, light brown fingerprint-like structures, or milia-like cysts. Lichenoid keratoses feature gray to blue granular pigmentation and a gray pseudonetwork on facial lesions. Pigmented actinic keratoses are notoriously difficult, at times, to differentiate dermoscopically from lentigo maligna;¹⁸⁶⁴ sometimes, the presence of black blotches¹⁸⁶⁴ or a scaly, rough surface¹⁰² can be used as a feature favoring the former diagnosis. With reflectance confocal microscopy, six key features have been identified that correlate with malignancy in lentigo maligna: nonedged papillae, round and large pagetoid cells, three or more atypical cells at the junction in five images, follicular location of pagetoid and/or atypical junctional cells, nucleated cells in the dermal papillae, and a broadened honeycomb pattern of the epidermis.¹⁸⁶⁵ Recurrent lesions of lentigo maligna show atypical melanocytes surrounding adnexal openings, cord-like rete ridges containing atypical melanocytes, and infiltration of adnexal structures by atypical melanocytes.¹⁸⁶⁶

Superficial spreading melanoma is characterized by a proliferation of atypical melanocytes, singly and in nests, at all levels within the epidermis. This pagetoid spread within the epidermis is sometimes known as 'buckshot scatter' (Fig. 32.38). Superficial adnexal epithelium may also be involved. Consumption of the epidermis is present in approximately 40% of cases of malignant melanoma of all types but only in a small number of cases with a benign diagnosis.¹⁸⁶⁷ Consumption is defined as thinning of the epidermis with attenuation of basal and suprabasal layers and loss of rete ridges adjacent to collections of melanocytes.¹⁸⁶⁷ It appears to be a precursor to ulceration. It may be a useful clue in the distinction between a melanoma and a Spitz nevus.⁵²⁰ Cleft formation is a related phenomenon.^{1868,1869} Cramer suggested that it is a reflection of aberrant melanocyte-keratinocyte interactions.¹⁸⁷⁰ The infiltrative component may be arranged in solid masses or may have a fascicular arrangement. The cells may be epithelioid, nevus cell-like, or even spindle-shaped without evidence of maturation during their descent into the dermis. Again, the degree of cytological atypia varies from case to case.¹⁸⁷¹

A rare variant of melanoma, usually of the superficial spreading type, is the **verrucous melanoma**.¹⁸⁷² This occurs most often on the back and limbs of middle-aged to older males.¹⁸⁷³ It is characterized by marked epidermal hyperplasia, elongation of the rete ridges, and

overlying hyperkeratosis.^{1874–1876} This variant is often misdiagnosed clinically as a seborrheic keratosis.¹⁸⁷² Another recently described variant is the superficial spreading melanoma composed predominantly of large nests, with few singly dispersed melanocytes in the epidermis and a lack of other diagnostic criteria for melanoma. Nests varied in size and shape, showed coalescence, and displayed variable cytologic atypia.¹⁸⁷⁷ Comparative genomic hybridization showed multiple genomic aberrations in these lesions.¹⁸⁷⁷

Automated detection of melanoma using *in vivo* reflectance confocal microscopy may be feasible, as demonstrated in a study by Gareau *et al.* A key discriminator for detecting pagetoid melanocytes versus surrounding epidermis is high reflectivity due to increased melanin granule content and possibly increased density of lipid membranes (which may prove to be helpful when faced with amelanotic lesions).¹⁸⁷⁸

Nodular melanoma has no adjacent intraepidermal component of atypical melanocytes, although there is usually epidermal invasion by malignant cells directly overlying the dermal mass. Heenan has challenged the validity of nodular melanoma as a discrete entity.¹⁸⁷⁹ The dermal component is usually composed of oval to round epithelioid cells, but as in other types of melanoma, this can be quite variable (Fig. 32.39). They are often thick melanomas.^{1713,1880,1881} Monster cells are rarely present.^{1882,1883} Such cases may sometimes resemble an atypical fibroxanthoma.^{1884,1885} Mast cells are increased in this and other types of melanoma.¹⁸⁸⁶ Erythrophagocytosis by tumor cells is an exceedingly rare phenomenon.¹⁸⁸⁷ Nestin, a marker for neural stem cells, is positive among HMB-45⁺ melanoma cells in the dermal component of nodular melanoma.¹⁸⁸⁸ Moreover, nestin expression is associated with increased tumor thickness, high mitotic count, tumor necrosis, and ulceration, and it is significantly associated with diminished survival.¹⁸⁸⁹ By multivariate analysis, the mitotic marker phosphohistone H3 (PHH3) has been shown to be a stronger prognostic indicator than mitotic count in the evaluation of nodular melanomas.¹⁸⁹⁰

Dermoscopic features favoring pigmented nodular melanoma over nodular nonmelanoma lesions are peripheral black dots/globules, multiple brown dots, irregular black dots/globules, blue-white veil, homogeneous blue pigmentation, five or six colors, and black color.¹⁸⁹¹ Another feature of importance is blue-black color (the 'BB feature'), consisting of a combination of blue and black pigmented areas involving at least 10% of the lesional surface. A combination of standard dermoscopic melanoma criteria and the 'BB feature' yielded a specificity of approximately 92% and a positive predictive value for malignancy of 91%.¹⁸⁹²

Figure 32.38 Superficial spreading melanoma. This lesion is level 1 (*in situ*). Atypical melanocytes show 'buckshot scatter' within the epidermis. (H&E)

Figure 32.39 Nodular melanoma. The tumor cells in the dermis have large, hyperchromatic nuclei. There is no melanin present in the cells. They were positive for S100 protein. (H&E)

Figure 32.40 Acral lentiginous melanoma (radial growth phase). There are atypical melanocytes within the basal layer that show only slight upward spread. (H&E)

Acral lentiginous melanomas have a radial growth phase that is characterized by a lentiginous pattern of atypical melanocytes, with some nesting (Fig. 32.40).¹⁷¹⁵ There may be some 'buckshot scatter' of melanocytes, but this is never as marked as in superficial spreading melanoma. The melanocytes may be plump with a surrounding clear halo, giving a lacunar appearance, or they may have heavily pigmented dendritic processes. Approximately 15% of cases are amelanotic.¹⁸⁹³ The epidermal component may look misleadingly benign.¹⁸⁹⁴ Against this background, the report of three patients from Japan with 'atypical melanosis of the foot' must be viewed with some reservations.¹⁸⁹⁵ It is possible that regression resulted in the bland histological appearances seen in these cases, which clinically resembled acral lentiginous melanoma, in which the epidermis is usually hyperplastic; focal ulceration may occur. The invasive component may consist of epithelioid cells or spindle cells, or it may resemble nevus cells. The presence of small nevus cells was associated with a worse prognosis in one study.¹⁸⁹³ Mitotic activity appears to be of importance in predicting the outcome of acral lentiginous melanomas.¹⁸⁹³ There may be a desmoplastic stromal response. Osteosarcomatous change has been reported in the stroma. It is not uncommon for tumor cells to have infiltrated the deep dermis or subcutaneous tissue by the time of diagnosis.¹⁸⁹⁶ The high-molecular-weight melanoma-associated antigen (HMW-MAA), a membrane-bound chondroitin sulfate proteoglycan found on the surface of melanoma cells, is expressed in more than 50% of acral lentiginous melanoma lesions, but mostly with weak staining intensity; this is in contrast to superficial spreading melanomas, in which staining for HMW-MAA is strongly positive.¹⁸⁹⁷

In the series of subungual melanomas reported from the Sydney Melanoma Unit, tumor-infiltrating lymphocytes were often present.¹⁷⁴⁸ Their presence favors melanoma over an acral nevus.¹⁷⁴⁸

Ahmed reviewed the histological spectrum of acral melanomas and proposed that this term be used for all melanomas in acral locations, not just those traditionally called acral lentiginous melanoma.¹⁸⁹⁸ In a significant number of these cases, the dermal component shows an unusual morphology, including the presence of giant, nevoid, and clear cells.¹⁸⁹⁸ Neural differentiation and perineural infiltration may also occur.¹⁸⁹⁹ Classification of acral lentiginous melanoma and other histologic subtypes is currently in flux (see p. 876).

Features that distinguish subungual melanoma *in situ* from subungual melanotic macules include pagetoid spread, multinucleated melanocytes, lichenoid inflammatory reaction, and the presence of confluent stretches of solitary units of melanocytes in melanoma *in situ*.¹⁹⁰⁰

Figure 32.41 Desmoplastic melanoma. Bundles of spindle-shaped cells are present in the dermis admixed with collagen and blood vessels. Note the characteristic lymphoid collections. This case was initially misdiagnosed as 'scar tissue'. (H&E)

Desmoplastic/spindle cell melanomas are composed of strands of elongated spindle-shaped cells surrounded by mature collagen bundles (Fig. 32.41). The stromal component varies considerably in different tumors. Sometimes there are scattered spindle cells and abundant collagen, whereas in others there is little stroma. This latter group is usually referred to as spindle cell melanoma. Although there may be emerging immunohistochemical and molecular data allowing distinction between desmoplastic melanoma and spindle cell melanoma,¹⁹⁰¹ these entities form a histologic continuum without a discrete separation.¹⁹⁰² Desmoplastic melanoma can be regarded as a fibrosing variant of spindle cell melanoma.¹⁹⁰³ Desmoplastic melanomas are subdivided into a 'pure' form when the lesion is entirely desmoplastic and a 'combined' form when the desmoplastic melanoma is mixed with conventional melanoma.¹⁷⁷⁶ The desmoplastic features are usually more prominent in the local recurrences, in contrast to lymph node and visceral metastases, which often resemble conventional melanomas, supporting the notion that 'pure' lesions have a better prognosis than 'mixed' and conventional melanomas of the same pathologic stage.¹⁹⁰⁴ The desmoplastic melanoma cells resemble fibroblasts, but there are scattered cells with hyperchromatic and even bizarre nuclei.¹⁹⁰⁵ Multinucleate cells are often present. Small foci of neural transformation and neurotropism may be seen.^{1784,1906} The tumor infiltrates deeply. The

Breslow thickness exceeds 4 mm in half of the cases.¹⁷⁷⁶ The full extent of the tumor is sometimes difficult to discern with accuracy. The use of S100 staining is a valuable adjunct in determining the extent of some lesions.¹⁹⁰⁷ Care must be taken not to misinterpret the S100⁺ spindle cells found in scar tissue as desmoplastic melanoma.¹⁹⁰⁸ There may be scattered collections of lymphocytes and plasma cells within the tumor. In paucicellular tumors, these small foci of inflammatory cells can provide a clue to the diagnosis on scanning magnification. This paucicellular variant is easy to misdiagnose on a small punch biopsy or superficial shave. There may even be a resemblance to dermatofibroma with a storiform appearance. Another variant is the superficial or early lesion characterized by cytological atypia, stromal myxoid change, aggregates of lymphocytes, and poor circumscription.¹⁹⁰⁹ Heterotopic bone and cartilage and sweat duct proliferation may form.^{1910–1913} Aggressive variants of osteogenic desmoplastic melanoma have been reported.¹⁹¹⁴ There is often a lentigo maligna epidermal component overlying or toward one edge of the lesion.¹⁷⁸² The tumor cells are nearly always amelanotic.

Immunohistochemistry is covered in detail on page 889, but several points specific to desmoplastic melanoma are discussed here. Desmoplastic melanomas are positive for vimentin in all cases and for S100 protein and neuron-specific enolase in approximately 95% of cases.^{1905,1915,1916} Staining for S100A6 has limited value in desmoplastic melanomas.¹⁹¹⁷ Sometimes only a minority of the malignant cells (10–20%) express S100 protein. HMB-45, which detects premelanosomes, is detected in 0–20% of cases, but only small clusters of cells are stained in the positive cases.^{1784,1916,1918} If desmoplastic/spindle cell melanomas are separated into two groups, pure desmoplastic melanomas are negative for gp100 (HMB-45).^{1919,1920} Nearly 50% of spindle cell melanomas show some staining for HMB-45, and this subset of tumors appears to have a more aggressive biological potential than negative lesions.¹⁹¹⁹ Sensitivity is increased if antigen retrieval methods are used.¹⁹²¹ MART-1 (melan-A) gives mostly negative results with desmoplastic melanoma and is of little use with this morphological type.¹⁹²² In contrast, the sclerotic/desmoplastic blue nevus is usually positive for MART-1 (melan-A).^{1923,1924} NKI/C3 is expressed in approximately one-fourth of cases.¹⁹¹⁶ In one study, MiTF had a sensitivity for desmoplastic/spindle cell melanomas that equaled or exceeded that of gp100 (HMB-45) or MART-1 (melan-A).^{1925,1926} In another series, it stained only one case of desmoplastic melanoma.¹⁹²⁷ To date, MiTF lacks sufficient sensitivity and specificity for widespread diagnostic use.^{1928,1929} Smooth muscle actin is present in a patchy distribution in nearly half of cases.^{1784,1930} Clusterin is expressed in approximately 30% of desmoplastic melanomas.¹⁹³¹ Basic fibroblast growth factor (bFGF), an established growth factor for melanocytes, and other fibrogenic cytokines are expressed in the nuclei of the tumor cells in most desmoplastic melanomas.¹⁰²³ They presumably play a role in mediating the desmoplastic phenotype.¹⁹³² p75 nerve growth factor receptor (also known as NGFR) stains the cells in desmoplastic and neurotropic tumors, but it also stains other tumors of putative neural crest origin.^{1918,1933–1935} It may be useful in cases of S100[−] desmoplastic melanomas.^{1936,1937} Basement membrane antigens such as laminin and type IV collagen are often expressed in spindle cell melanomas.¹⁹³⁸ Despite showing relatively low numbers of mitotic figures, desmoplastic melanomas usually display high numbers of Ki-67⁺ cells,¹⁹³⁹ although one study found that Ki-67 was an inconsistent marker, a labeling index greater than 5% may be used as a clue in diagnosing desmoplastic melanomas.¹⁹²³ CD34 expression has been reported in a metastatic desmoplastic melanoma.¹⁹⁴⁰ Although mature scars are easily differentiated from desmoplastic melanoma on light microscopy, immature scars share many features, including lymphoid infiltrates, myxoid change, hypercellularity, and atypia.¹⁹⁴¹ Scars may also express p75 (NGFR)¹⁹⁴² and S100 protein.¹⁹⁰⁸ Parallelism of fibrocyte nuclei may be present in scar tissue. Nuclei in desmoplastic melanoma have a haphazard array.

Figure 32.42 (A) Neurotropic melanoma. (B) Tumor cells are loosely arranged in a concentric manner around a small nerve in the subcutis. Lymphocytes are present in the surrounding tissue. (H&E)

In the **neurotropic** variant, which accounts for approximately one-third of all cases of desmoplastic melanoma¹⁷⁷⁶ (**Fig. 32.42**), there are spindle-shaped cells with neuroma-like patterns (neural transformation) and a tendency to adopt a circumferential arrangement around small nerves in the deep dermis and subcutaneous tissue (neurotropism).^{1771,1943,1944} Interlacing bundles of cells are seen. Desmoplastic and neurotropic patterns often occur together in the same neoplasm.¹⁹⁴⁵ The cells vary in size and nuclear staining. The cells usually lack melanin pigment, although a case with prominent melanization of the cells has been reported.¹⁹⁴⁶ The absence of S100 protein using immunoperoxidase techniques does not exclude the diagnosis, with one study reporting absence of S100 in up to 20% of cases.¹⁹⁴⁷ Staining for p75 can be used in these circumstances.¹⁹³⁷ There is a significant risk of local recurrence in the presence of neurotropism.¹⁷⁸⁷ A collision tumor involving a squamous cell carcinoma and a neurotropic melanoma has been reported.¹⁹⁴⁸

'Minimal deviation melanoma' is the term applied to melanomas in which the vertical growth phase is composed of a uniform population of cells whose cytological features deviate only minimally from those of nevus cells.^{1949–1954} Epithelioid or spindle cell features may be present. Included in this group by some pathologists is the melanoma composed of cells resembling small nevus cells (see p. 885). The concept of minimal deviation melanoma has not gained universal acceptance, largely because of an absence of standardized histological criteria.^{1955–1958}

There is evidence that this diagnosis has been applied indiscriminately to difficult and borderline lesions. In a review of unusual variants of melanoma, Magro *et al.* stated that minimal deviation melanoma is a distinct clinicopathological entity.¹⁹⁵⁹

Associated nevi

A contiguous nevus, either dysplastic or common (banal) type, is found in approximately one-fourth to one-third of all melanomas.^{1960–1963} The nevus is more often of acquired than congenital type, although in some instances a distinction cannot be made. The vast majority of the acquired nevi found in association with melanomas are of the dysplastic (atypical) type.¹⁹⁶⁴ Melanomas develop only rarely from intradermal nevi (see p. 887).¹⁹⁶⁵ Nevi that undergo malignant change may result in melanomas that are thicker than *de novo* melanomas.¹⁹⁶⁶

Regression

Partial regression may be found in up to one-third of melanomas,^{1967,1968} the figure is higher in thin melanomas.^{1969–1972} Active regression is recognized by the presence of a heavy lymphocytic infiltrate in the dermis, with loss or degeneration of tumor cells.¹⁹⁷³ This infiltrate may have lichenoid (interface) qualities that obscure a major portion of the lesion.¹⁹⁷⁴ It seems likely that tumor cells are removed by lymphocyte-mediated apoptosis. Previous (old) regression is characterized by the presence of vascular fibrous tissue with or without melanophages and also a variable lymphocytic infiltrate.¹⁹⁷³ If numerous melanophages are present, the term ‘**nodular melanosis**’ is sometimes used. This pattern is not exclusive to regressed melanomas;¹⁹⁷⁵ it can be produced by the regression of solar lentigines and epithelial lesions, such as a pigmented basal cell carcinoma.^{1976,1977} It has been suggested that because the different stages of regression often coexist in the one specimen, ‘subdividing the process is impractical and unrealistic’.¹⁹⁷⁸ The prognostic significance of partial regression is considered later (see p. 892).

Vitiligo-like hypopigmentation may occur at sites distant from a melanoma. Pigment-related ocular disturbances may also occur.¹⁹⁷⁹ The depigmentation is sometimes related to regression of the lesion or the development of metastases.¹⁹⁷⁹

Approximately 2% of patients with melanoma present with metastatic disease in the absence of a recognized primary tumor.¹⁹⁸⁰ In many of these cases of so-called ‘occult primary melanoma’, it is probable that the primary lesion underwent spontaneous regression.¹⁹⁸¹ Sometimes the patient can recall an earlier pigmented lesion that enlarged, darkened, and then flattened and depigmented.¹⁹⁸² Histological examination of such a site may reveal evidence of microscopic disease.¹⁹⁸³ Complete regression appears to be associated with a poor outcome.¹⁹⁸⁴ Other possibilities for the absence of a cutaneous primary include origin of the tumor in lymph nodes or in visceral organs, or a primary cutaneous lesion that is initially undetectable.¹⁹⁸⁵ A related phenomenon is the occurrence of a single focus of melanoma, of presumed metastatic origin, confined to the dermis and/or subcutis but without evidence of an overlying epidermal component or inflammation. Such tumors may be the result of previous partial regression of which no evidence remains, or local recurrence following previous complete regression. Such cases have a better prognosis than other examples of stage IV disease, suggesting that they are not true metastases.¹⁹⁸⁶ Such cases are now regarded as a discrete entity, termed primary dermal melanoma (see later).

Differential diagnosis of the major types of melanoma

Note that differential diagnostic considerations for nevoid melanomas are considered in that section (p. 885).

Of considerable concern in the differential diagnosis of melanoma is its differentiation from atypical or dysplastic melanocytic nevi. There is currently no easy solution to this conundrum using standard morphologic interpretation or even, at times, immunohistochemical staining. The basic approach is to examine each section carefully and

obtain additional levels – and consultation – in difficult cases. Features favoring melanoma as opposed to a nevus include prominent pagetoid change (realizing, however, that such changes can be seen focally in variants of Spitz nevus and ‘special site’ nevi, especially those from acral sites), rete ridge effacement, confluence of junctional melanocytes sufficient to fill entire high-power fields, band-like dermal inflammation, and adnexal involvement (which, again, can also be seen in some nevi, particularly from special sites such as the breast). Close attention to the degree, type, and extent of cytologic atypia is also important. However, there are certain lesions for which a clear distinction between atypical nevus and melanoma is not possible. In these cases, reports should indicate that the lesion in question is an atypical melanocytic process of uncertain biologic potential, and a recommendation for complete excision and close clinical follow-up is warranted. It is hoped that molecular analysis might facilitate resolution of these diagnostic dilemmas in the future.

Superficial spreading melanomas should also be distinguished from other pagetoid lesions, such as Paget’s and extramammary Paget’s disease and pagetoid Bowen’s disease. The first two disorders are composed of cells with abundant, pale cytoplasm (generally positive with mucin stains) that are often separated from, and may compress, the epidermal basilar layer. Bowen’s disease shows atypia and loss of maturation of nonpagetoid as well as pagetoid cells. Differential immunostaining can resolve difficult cases; melanoma cells mark with the usually melanocytic stains, whereas both extramammary Paget’s disease and Bowen’s disease cells express keratins, and Paget cells are reactive for carcinoembryonic antigen and gross cystic disease fluid protein-15. Paget cells sometimes contain melanin, but they do not express melanocytic markers.

Lentigo maligna should be distinguished from solar lentigo, in which there may be substantial junctional melanocytic hyperplasia. ‘Starburst’ giant cells are sometimes seen in lentigo maligna and are not encountered in melanocytes in sun-damaged skin, although they may be encountered in benign melanocytic lesions.^{1857,1858} A diagnosis of lentigo maligna requires finding significant confluence of junctional melanocytes as well as cytologic atypia; that search can be aided by close examination of multiple levels and immunostaining. Our favorite approach is to stain for melan-A using the diaminobenzidine method and with azure B counterstaining (which stains melanin blue-green). Bowen *et al.* found microscopic features usually associated with lentigo maligna in uninvolved, sun-damaged skin, including melanocyte confluence, adnexal extension, melanocyte stacking, nested collections of melanocytes, and occasional pagetoid changes. These changes are less prevalent and more focal than observed in actual lesions, but they can create confusion when attempting to determine surgical margins and adequacy of re-excision specimens.¹⁹⁸⁷ The authors recommend using control biopsies of uninvolved, sun-damaged skin to aid in the differentiation of lentigo maligna from background UV damage.¹⁹⁸⁷ Magro *et al.* investigated the use of the R21 antibody directed toward soluble adenylyl cyclase (sAC), an enzyme that generates cyclic AMP, a signaling molecule that regulates melanocyte proliferation and melanogenesis. Using a protocol that eliminates non-melanocytic staining, the authors found nuclear staining in lentigo maligna with a sensitivity of greater than 87%.¹⁹⁸⁸ The technique can also be used to assess surgical margins; positive staining of nine or more cells and/or an SAC:melan-A ratio of approximating 1 is associated with histologically positive margins.¹⁹⁸⁸ Sethi *et al.* found that macromelanosomes are present in lesional margins of 21% of lentigo malignas but in only 1% of examples of solar lentigines; this suggests that the detection of macromelanosomes in a lentiginous lesion should prompt further evaluation for the possibility of a contiguous lentigo maligna, particularly in the setting of a small biopsy specimen.¹⁹⁸⁹

Nodular melanomas, by definition, lack clear evidence for the radial growth phase components seen in the other types of melanoma. Therefore, the dermal tumor may resemble a variety of other lesions,

including Spitz nevi, conventional melanocytic nevi in the case of nevoid melanoma (see later), and cellular blue nevi. Spindle cell variants at times resemble spindle cell squamous cell carcinoma or atypical fibroxanthoma. Cytologic atypia, mitotic activity, and lack of maturation descent should help distinguish nodular melanoma from benign melanocytic lesions, whereas differential immunostaining can exclude squamous cell carcinoma or atypical fibroxanthoma.

Acral lentiginous melanoma has some features resembling acral nevi, including pagetoid intraepidermal change, intradermal nesting patterns, syringotropism, inflammation, and fibroplasia. On the other hand, acral lentiginous melanomas have higher grade cytologic atypia and mitotic activity, and they lack evidence of dermal maturation descent, with transition to scattered single cells at the lesional base – findings usually seen in acral nevi.

Desmoplastic melanomas are frequently positive for S100 but fail to stain with other ‘traditional’ melanocytic markers. Therefore, these lesions can be confused with other spindle cell-predominant lesions, ranging from dermal scars to soft tissue sarcomas. Some of the newer immunohistochemical stains, such as KBA.62 and SOX-10, may help in reaching a correct diagnosis and determining clear surgical margins (see the section titled [Special Techniques to Aid Diagnosis](#)).

Special histologic variants of melanoma

In recent years, a number of histologically distinct variants of malignant melanoma have been described.^{1959,1990} They were reviewed in 2005 by Rongioletti and Smoller.¹⁹⁹¹ Divergent differentiation in melanomas was also reviewed in 2008 by Banerjee and Eyden.¹⁹⁹² These variants are listed in [Table 32.5](#). Some of these have been referred to previously because they represent unusual histological changes in one of the major categories of melanoma. Included in this category are the *melanomas with monster cells*.^{1882,1883} Smooth muscle differentiation has been reported in one case of a metastatic sarcomatoid melanoma in an axillary lymph node.¹⁹⁹³ Cases of desmoplastic melanoma with positivity for smooth muscle actin have also been reported.¹⁹⁹¹ Psammoma bodies were present in another case.¹⁹⁹⁴ The tumor referred to as *adenoid-cystic melanoma* and *pseudopapillary melanoma* would be best called ‘*cystic melanoma*’.¹⁹⁹¹ A melanoma variant that resembles

acantholytic dermatoses has been described.¹⁹⁹⁵ The *schwannoid melanoma* has rows of melanoma cells with palisading nuclei resembling Verocay bodies.¹⁹⁹¹ The *plasmacytoid melanoma* has aggregates of plasmacytoid melanoma cells with eccentric nuclei and abundant cytoplasm.¹⁹⁹⁰ A few cases of melanoma and nevi have been reported with sebocyte-like melanocytes.^{1996,1997} Syringotropic melanomas may show deep dermal extension within the eccrine apparatus. This syringocentric involvement must be taken into consideration when re-excising these lesions and when providing prognostic and staging information.¹⁹⁹⁸ These findings do not warrant special consideration as discrete entities.

Follicular melanoma

Follicular melanoma, described in 2004, is an exceedingly rare variant of melanoma found in elderly patients.¹⁹⁹⁹ There is a predilection for the nose. It is characterized by a deep-seated follicular structure in which atypical melanocytes extend downward along the follicular epithelium and permeate parts of the follicle as well as the adjacent dermis.¹⁹⁹⁹ There has been a recent example of a metastatic variant of follicular melanoma.²⁰⁰⁰ The tumor mostly resembles a comedo or a pigmented cyst. The lesions would have been missed by superficial shave biopsy.¹⁹⁹⁹ The tumor cells express melan-A, S100 protein, and gp100 (HMB-45).

The case reported by Carrera *et al.* in 2007 as ‘*seborrheic keratosis-like melanoma with folliculotropism*’ was similar in many ways to follicular melanoma.²⁰⁰¹

Myxoid melanoma^{2002–2008}

The myxoid variant was first described in a metastatic deposit, but it has since been described in primary lesions as well.^{2009,2010} Spindle- and stellate-shaped cells are embedded in a myxoid stroma. A myxoid metastatic deposit has been reported, although the primary melanoma was non-myxoid.²⁰¹¹ The stroma stains with Alcian blue, and the tumor cells express S100 protein and neuron-specific enolase. A case with a prominent clear stroma that did not stain with Alcian blue has been called a ‘melanoma with pseudomyxoid features’.²⁰¹² gp100 (HMB-45) may not be expressed, despite the presence of premelanosomes in one case examined ultrastructurally.²⁰⁰⁵ However, gp100 (HMB-45) was present in 9 of 10 cases in a more recent study.²⁰¹³ Mast cells and transforming growth factor-β are increased in myxoid melanoma, and these factors may be responsible for stimulating fibroblasts to produce mucin.²⁰¹⁴

Balloon cell melanoma

Balloon cell change may occur in primary or secondary melanomas ([Fig. 32.43](#)).^{1784,2015,2016} A metastatic balloon cell melanoma has been described in which balloon cells were only a minor component of the primary lesion.²⁰¹⁷ The presence of nuclear pleomorphism, mitoses, and cytological atypia help to distinguish this lesion from balloon cell nevus (see p. 849). The cells express the usual immunohistochemical markers of a malignant melanoma. The prognosis correlates with tumor thickness.²⁰¹⁸ The nature of the clear cell change is uncertain; it is not a degenerative change, as was once thought.²⁰¹⁹ It should be distinguished from the *pseudolipoblastic melanoma*, in which the vacuolated cells resemble lipoblasts.^{1990,1991} Both changes have been reported concurrently in a metastatic balloon cell melanoma.¹⁹⁹⁰

Dermoscopic features in one case included ‘chaos’ (asymmetry of structure and/or color – in this case, due to a pigmented non-balloon cell component); an eccentric, structureless white area; polymorphous vessels; and polarizing-specific white lines or chrysalis structures.²⁰²⁰

Signet-ring cell melanoma

The presence of signet-ring cells has been reported in several metastatic and recurrent melanomas and also in at least two primary lesions ([Fig. 32.44](#)).^{2021–2026} Pseudoglandular features were also present in one

Table 32.5 Histologic variants of melanoma	
Acantholytic-like melanoma	Melanoma with rosettes
Angiomatoid melanoma	Melanoma with sebocytes
Angiotropic melanoma	Myxoid melanoma
Animal-type melanoma (pigmented epithelioid melanocytoma)	Neuroendocrine melanoma
Balloon-cell melanoma	Nevoid melanoma
Bullous melanoma	Osteogenic melanoma
Chondroid melanoma	Plasmacytoid melanoma
Clear cell sarcoma (melanoma of soft parts)	Pseudoglandular melanoma
Cystic (adenoid cystic) melanoma	Pseudolipoblastic melanoma
Dermal melanoma	Rhabdoid melanoma
Follicular melanoma	Sarcomatoid melanoma
Ganglioneuroblastic melanoma	Schwannoid melanoma
Lentiginous melanoma	Signet-ring cell melanoma
Melanocarcinoma	Small cell melanoma
Melanoma mimicking Merkel cell carcinoma	Small-diameter melanoma
Melanoma resembling MPNST	Spitzoid melanoma
Melanoma with monster cells	Syringotropic melanoma
Melanoma with psammoma bodies	Vitiligo-like melanoma

Figure 32.43 Balloon cell melanoma. The distinction from balloon cell nevus is largely based on the presence of cytological atypia. (H&E)

Figure 32.44 Signet-ring cell melanoma. The cells have an eccentric nucleus and foamy cytoplasm. (H&E)

case.²⁰²⁷ These cells are quite different from the scattered sebocyte-like cells occasionally seen in nevi and metastatic melanoma.^{1996,1997}

Pseudoglandular melanoma

This variant of melanoma is exceedingly rare. Atypical melanocytes are arranged in a well-structured glandular pattern.²⁰²⁸ They express S100 protein. This variant has also been described in melanomas metastatic to glandular organs.²⁰²⁸ The melanoma with rosettes is morphologically related.²⁰²⁹

Rhabdoid melanoma

The presence of cells resembling those seen in rhabdoid tumors (see p. 1038) is a rare change described in metastatic melanomas.^{2030,2031} It has since been reported in primary melanomas.^{2032,2033} Large pleomorphic multinucleated cells can be seen in a rare variant that masquerades as malignant fibrous histiocytoma.²⁰³⁴ The immunohistochemical profile of rhabdoid melanomas is variable. Most are S100 and vimentin positive.²⁰³⁵ A few also express gp100 (HMB-45). A few cases are negative for all melanoma markers.

Osteogenic melanoma

Osteocartilaginous metaplasia is an exceedingly rare finding in malignant melanomas.^{2036,2037} The change usually occurs in acral lentiginous melanomas, particularly subungual lesions.²⁰³⁸ There is a high-grade sarcomatoid component, with osteoid matrix and sometimes chondroblastic differentiation. Junctional activity assists in making the diagnosis. The cells are positive for S100 protein and vimentin. Staining with HMB-45 is variable. Osteocartilaginous differentiation has been described in two cases of primary mucosal melanoma.²⁰³⁹ Melanomas with osteoclast-like giant cells have also been reported.^{2040,2041}

Chondroid melanoma

Prominent cartilaginous differentiation simulating chondrosarcoma is an extremely rare form of melanoma.^{2042,2043} There is no associated osteoid formation in this variant. A chondroid melanoma metastatic to lung and skin showed SOX-9 expression – a finding that led to an initial interpretation of myxoid chondrosarcoma (SOX9 expression is characteristic of myxoid chondrosarcoma but can also be seen in 84% of melanomas, including tumors lacking cartilaginous differentiation).²⁰⁴⁴

Small cell melanoma

Small cell melanoma refers to the presence of cells resembling those seen in a Merkel cell carcinoma (see p. 1062). It has also been used for a variant of nevoid melanoma (see later), but some cases of nevoid melanoma composed of small cells are included in the category of small cell melanoma.^{2045,2046} In one reported non-nevoid case, the cells were focally positive for S100 protein and strongly positive using HMB-45. A recent case of metastatic small cell melanoma resembled lymphoma on fine needle aspiration cytology; flow cytometry surprisingly showed positivity for CD43, but S100 and HMB-45/MART positivity confirmed the diagnosis of melanoma.²⁰⁴⁷ The cells contained premelanosomes and melanosomes on electron microscopy.²⁰⁴⁸ Spatz and Barnhill and Blessing *et al.* have proposed the use of the term ‘small cell melanoma’ for a variant of nevoid melanoma in which more than 50% of the melanoma cells have nuclei smaller than keratinocytic nuclei.^{2049,2050}

The cases reported as malignant melanoma with neuroendocrine differentiation (*neuroendocrine melanoma*) were composed of small cells expressing melanocytic and neuroendocrine markers.²⁰⁵¹ Sometimes the cells were larger and epithelioid.

Nevoid (and Spitzoid) melanoma

The existence of a melanoma composed of nevus-like cells has been known for a long time, but only comparatively recently has it been separated from nodular melanoma.²⁰⁵²⁻²⁰⁵⁵ It sometimes causes problems in diagnosis.^{1840,2056} Two histological variants of nevoid melanoma are now recognized: one composed of small nevus-like cells (Fig. 32.45) and the other composed of larger cells resembling those seen in a Spitz nevus.^{2052,2057,2058} Spitzoid melanoma is the preferred term for the latter. Mixed variants are rare. Recently described Spitzoid tumors and melanomas with inactivation of *BAP1* are considered separately (p. 898). The term ‘small cell melanoma’ (discussed previously) is often used for the small cell variant of nevoid melanoma. Many restrict use of the term ‘nevoid melanoma’ to lesions that resemble a benign nevus and that do not possess an intraepidermal component resembling the radial growth phase of one of the more usual types of melanoma (Fig. 32.46). Kossard and Wilkinson included as nevoid melanomas cases composed of small cells in the dermis, all but one of which had a lentiginous intraepidermal component.²⁰⁵⁹

Nevoid melanomas superficially resemble a nevus by their cell type, symmetry, and lack of a prominent intraepidermal component. They may even show maturation of cells in depth, although this is often impaired.²⁰⁶⁰ The diagnosis can be made by the presence of often mitoses, often deep, and cells in the base with prominent nucleoli. The cells often form sheets or cords in part of the lesion, with the loss

Figure 32.45 (A) Melanoma composed of small nevus-like cells. (B) Tumor cells surround a small nerve in the deep dermis. The patient developed metastases one year after the removal of this lesion. (H&E)

Figure 32.46 Nevoid melanoma. This case was initially diagnosed as benign, but it metastasized. There is variability in nest size and arrangement. (H&E)

of an orderly arrangement of nests. Subtle pleomorphism is often present.²⁰⁶⁰ An epidermal verrucous pattern with prominent acanthosis is sometimes seen in the ‘Spitzoid’ variant.^{2054,2060} The continuous pattern of melanocytes along the basal layer helps distinguish this lesion from a Spitz nevus. Historically, the increased number of AgNORs (see p. 890) has been used to assist in the diagnosis of these lesions.²⁰⁶¹ More recently, FISH and CGH studies (see p. 890) have helped characterize Spitz nevi and Spitzoid melanoma. Polysomy (specifically, tetraploidy) and gains in 11p are commonly observed in Spitz nevi. Spitzoid melanomas commonly show homozygous loss of 9p21 (p16).⁵⁷¹ The latter does not correlate with p16 expression by immunohistochemistry.²⁰⁶² In contrast to the majority of cutaneous melanomas, activating hot-spot mutations in *BRAF* or *NRAS* are not involved in the pathogenesis of Spitzoid melanomas.²⁰⁶³

McNutt and colleagues studied the immunohistochemical features of nevoid melanomas. They express S100 protein, gp100 (HMB-45), PCNA, and Ki-67 (using the antibody MIB-1). In contrast, a Spitz nevus usually shows stratification of staining (not always with PCNA), with less intense staining of cells in the base of the lesion.^{2052,2064} In a metastatic nevoid melanoma in a 4½-year-old child, the cells in the primary lesion expressed S100 protein, gp100 (HMB-45), MART-1, and cyclin D1.²⁰⁶⁷ Approximately 10% of the cells stained with MIB-1.²⁰⁶⁵ More recently, neuropilin-2 was used to distinguish Spitz nevi from Spitzoid melanoma.⁵⁶⁵ In this study, 19/19 Spitzoid melanomas expressed neuropilin-2, whereas only 5/19 of Spitz nevi were positive.⁵⁶⁵ CD99 expression also favors a diagnosis of Spitzoid melanoma over a Spitz nevus.⁵⁶⁴ Although one study has shown a better than expected prognosis for nevoid melanomas,²⁰⁵⁴ this has not been confirmed.^{2052,2053}

Vitiligo-like melanoma

Although depigmentation around nevi and melanomas is a well-documented event, usually related to regression, primary melanoma presenting as a vitiliginous patch without histopathological evidence of regression seems to be a rare event.^{1705,2066} It may be considered a variant of amelanotic melanoma.¹⁷⁰⁵

Small-diameter melanoma

Approximately 5% of melanomas are less than 6 mm in diameter.^{2067–2070} This percentage appears to be increasing.²⁰⁷¹ These lesions tend to occur in patients younger than the usual average age for melanoma. They usually arise *de novo*.²⁰⁷² Initially, they were thought to have a better prognosis than melanomas of the same thickness, but this does not appear to be the case. The number of small-diameter melanomas does not negate the utility of lesion diameter in the ABCDE acronym

for the clinical diagnosis of melanoma.²⁰⁷³ Dermoscopy of small-diameter melanomas had a sensitivity of 83% and a specificity of 69% in one series.²⁰⁷⁴ Computer-vision systems can facilitate early detection of this type of melanoma.²⁰⁷⁵

Ganglioneuroblastic melanoma

A case of metastatic melanoma showing ganglioneuroblastic differentiation has been reported. It combined large ganglion cells with abundant cytoplasm separated by pale pink fibrillar material.²⁰⁷⁶ Other areas resembled an epithelioid melanoma. The ganglioneuroblastic component stained for S100 protein, melan-A, neurofilament, GFAP, synaptophysin, and chromogranin.²⁰⁷⁶ A primary cutaneous melanoma with ganglioneuroblastic differentiation has now been reported.²⁰⁷⁷

Angiomatoid melanoma

The term 'angiomatoid melanoma' has been used for metastatic lesions in which the tumor cells show features suggesting vascular differentiation.^{2078,2079} It should not be confused with *angiotropic melanoma* (see p. 888), in which there is periendothelial cuffing of microvessels by melanoma cells.¹⁹⁹¹

Melanoma resembling MPNST

In 1999, 16 cases of metastatic malignant melanoma resembling malignant peripheral nerve sheath tumor (MPNST) were reported.²⁰⁸⁰ Histologically, the tumors were composed of an atypical spindle cell proliferation arranged in fascicles, often accompanied by a peritheliomatous growth pattern.²⁰⁸⁰ Foci of necrosis and numerous mitoses were often seen. Strong, diffuse staining for S100 protein was usually present.²⁰⁸⁰ Subsequent reports have shown that this pattern may also be found in primary malignant melanomas.^{2081,2082} The diagnosis can be difficult if there is no atypical epidermal component.²⁰⁸²

Dermal melanoma

Primary dermal melanoma has been referred to previously in the context of a presumptive dermal metastasis without an epidermal component but with a better prognosis than would be expected for stage IV disease.¹⁹⁸⁶ Swetter *et al.* described seven cases in 2004 with a mean Breslow depth of 7.0 mm and a 100% survival at mean follow-up of 41 months (range, 10–64 months).²⁰⁸³ Their cases conformed to the initial concept of a dermal and/or subcutaneous nodule that simulates a metastasis but with long survival. No background nevus was present in these cases or in the expanded series of 13 cases reported recently from the same institution.²⁰⁸⁴ In this recent series, two patients developed satellite or in-transit recurrences, one developed pulmonary metastasis, and another died of liver metastases. These cases showed lower levels of staining for the antigens p53, Ki-67, cyclin D1, and podoplanin lymphovascular staining compared with other melanomas.²⁰⁸⁴

Not included in this concept are cases of melanoma that arise in the deep intradermal component of a small nevus, either congenital or acquired.^{1965,2085} Massi and LeBoit stated that many of these cases are not melanomas but, rather, examples of combined nevi.²

Lentiginous melanoma

Lentiginous melanoma was first described in 2005 by King *et al.*²⁰⁸⁶ Subsequent reports have appeared,^{2087,2088} although dissenters exist.²⁰⁸⁹ This is the same entity that is described in this book as 'lentiginous dysplastic nevus of the elderly' (see p. 866). Lentiginous melanoma is likely to become the accepted terminology in keeping with modern-day practice of abandoning the concept of precursor lesions, as has already occurred with lentigo maligna (see p. 879). It may have medicolegal rather than scientific merit.

Animal-type (equine) melanoma

The rare animal-type variant of melanoma, also known as malignant melanoma with prominent pigment synthesis, is jet black in color and

composed of heavily pigmented epithelioid and dendritic cells with numerous melanophages. It may occur at any site, but several personally studied cases have been on the scalp.¹⁶⁰⁰ An oral melanoma with these features has been reported.²⁰⁹⁰ It resembles the tumor seen in many gray horses, which is a slow-growing, progressive lesion; it is usually benign in horses. In humans, its behavior has been unpredictable, with metastasis recorded in several cases.^{1959,2091,2092} This variant of melanoma is now included in the concept of 'pigmented epithelioid melanocytoma'. It is discussed as a discrete entity (see p. 898) and not as a variant of melanoma.

Melanocarcinoma

Although only one case of a melanoma with an intermixed epithelial component has been reported, it appears sufficiently distinctive to warrant separate consideration.²⁰⁹³ The term 'melanocarcinoma' seems appropriate. The tumor was composed of a spindle cell component, positive for the usual melanoma markers, and a glandular component with eccrine features that expressed the cytokeratin markers CAM5.2 and AE1/AE3.²⁰⁹³

Bullous melanoma

The presence of suprabasal clefting in a melanoma has been regarded as a possible localized manifestation of paraneoplastic pemphigus.²⁰⁹⁴ Subepidermal clefting has also been reported.¹⁸⁶⁹ The author has seen two cases in which the clefting was subepidermal and quite extensive (Fig. 32.47).

Recurrence

True local recurrence means clinically detectable regrowth of parts of the tumor that were not completely excised.²⁰⁹⁵ The term is often used for other events, such as satellite and in-transit metastasis. It may be associated with increasing tumor thickness, locality, and noncompliance with recommended excision margins.²⁰⁹⁵ In one study, 1.4% of all patients had a local recurrence as a first recurrence.²⁰⁹⁵ Heenan believes that there are two mechanisms of local recurrence.²⁰⁹⁶ One is due to persistent growth of incompletely excised primary melanoma, and the other is caused by local metastasis often hematogenous in origin, rather than lymphatic.²⁰⁹⁶ This concept has important implications for the width of margins of excision.

Metastases

The presence of metastases indicates a poor prognosis; the long-term survival rate is only 5%.²⁰⁹⁷ Metastases in cases of malignant melanoma are usually to regional lymph nodes in the first instance. The probability of nodal metastases is associated with Breslow tumor depth and

Figure 32.47 Bullous melanoma. The lesion presented as a pigmented blister. Acantholytic melanoma cells are in the subepidermal space. (H&E)

other histologic parameters (see p. 892). Nodal metastases are quite uncommon in lesions less than 1 mm in thickness; their frequency exceeds 50% among lesions greater than 4 mm in thickness.^{2098,2099} It has been suggested that the propensity for spindle cell melanomas to metastasize to lymph nodes is relatively low, despite their thickness.¹⁹⁰² Metastases also involve the skin and subcutaneous tissue,^{2100,2101} skin graft donor sites,²¹⁰² lungs, brain and dura,²¹⁰³ gastrointestinal tract, palatine tonsil,²¹⁰⁴ heart,²¹⁰⁵ liver, and adrenal glands.²¹⁰⁶ These distant metastases are often due to hematogenous spread, which accounted for 28% of metastases in one study.²¹⁰⁷ Nodal and pulmonary granulomatosis, usually of sarcoidal type, is a rare finding in patients with malignant melanoma.²¹⁰⁸ Its presence may lead to a clinical misdiagnosis of metastatic disease. Fine needle aspiration can be used as a reliable technique to diagnose metastatic melanoma.^{2109,2110} Rarely, dermal lymphatic invasion associated with cutaneous metastatic disease may give a picture resembling that of so-called 'inflammatory' carcinoma of the breast.^{2111–2115}

The lymphatic marker D2-40 has shown many intratumoral lymphatics in melanoma,²¹¹⁶ as well as lymphatic invasion.²¹¹⁷ Nevertheless, lymphatic permeation in primary cutaneous melanoma is rarely seen in H&E sections;²¹¹⁸ however, it is the likely cause of in-transit metastases.²¹¹⁹ Such metastases are clonal in type.²¹²⁰ Sometimes genetically heterogeneous and clonally unrelated metastases are present.²¹²¹ Rare cases of blood vessel wall invasion (*angiotropic melanoma*) have been reported.^{2079,2122–2125} This usually takes the form of periendothelial cuffing (in a pericytic location along the endothelium) of microvessels by melanoma cells, although extension of cells throughout the vessel wall may occur.^{2126–2128} Melanoma cells, like glioma cells, may migrate in an extravascular plane, particularly along the abluminal surface of vessels.²¹²⁹ Melanoma cells can also form vascular channels – a process that has been termed 'vasculogenic mimicry'.²¹³⁰ A study from the Sydney Melanoma Unit found that angiotropism was an independent predictor of local recurrence and in-transit metastasis in primary cutaneous melanoma.²¹³¹ Other tropic phenomena (neurotropism and eccrine duct tropism) may accompany the vascular lesions.²¹²⁶

When cutaneous metastases of malignant melanoma extend into the epidermis (epidermotropic metastases), differentiating them from a primary melanoma can be particularly difficult.²¹³² The epidermotropic component can extend beyond the dermal component – a finding that used to be regarded as specific for a primary lesion.²¹³² Even an epidermis-only pattern of epidermotropic metastasis can occur. The pattern seen in local recurrences can be identical.^{2133,2134} Rarely, cutaneous metastases of malignant melanoma are histologically bland and difficult to diagnose.²¹³⁵

The development of *generalized melanosis* in patients with malignant melanoma has been attributed by some to an unlimited spread of single melanoma cells throughout the dermis,^{2136–2138} but others have specifically excluded the presence of tumor cells and have found numerous perivascular melanophages in the dermis.^{2139–2142} Pigment may also be present in endothelial cells.²¹⁴¹ Several cases of melanosis associated with placental metastasis of the maternal melanoma have been reported.²¹⁴³ One study attributed the pigmentation to activation of the pigment system by melanocyte peptide growth factors and not to widely dispersed melanoma cells.²¹⁴⁴ Exceptions appear to occur. Melanuria is another complication of metastatic melanoma.²¹⁴⁵ In patients with metastatic disease involving the urinary tract, tyrosinase reverse-transcriptase polymerase chain reaction (RT-PCR) is more sensitive than traditional urinary cytology in detecting urinary melanoma cells.²¹⁴⁶

One rare complication of treatment of metastatic disease warrants mention – the tumor lysis syndrome. This complication, seen mostly with hematological malignancies, results from the rapid death of numerous malignant cells releasing intracellular products that overwhelm the renal tubules, producing metabolic derangements that may end in death. It has been reported in a patient with metastatic

melanoma.²¹⁴⁷ Topical imiquimod has even been used to treat skin metastases of melanoma.²¹⁴⁸

In a study published in 2004 that assessed the sensitivity of routine immunohistochemical markers on metastatic deposits in lymph nodes, 98% of cases (123 of 126) stained positive for S100 protein, 93% for NK1/C-3, 82% for MART-1 (melan-A), and 76% for gp100 (HMB-45).²¹⁴⁹

Multiple primary lesions

Additional primary melanomas may develop in 2–5% of patients with malignant melanoma.^{2150–2156} Up to one-third are diagnosed concurrently with the initial melanoma.²¹⁵⁷ A significant number are diagnosed in the first few months after the removal of the initial lesion.²¹⁵⁸ Sometimes it is difficult to distinguish between a new primary lesion and an epidermotropic metastasis.^{2159,2160} The usually accepted criteria for diagnosing an additional primary lesion, as opposed to a cutaneous secondary – that is, junctional activity extending beyond the dermal component, lack of central epidermal attenuation, and lack of lymphatic permeation – may not always be reliable (discussed previously).²¹⁶⁰ The second primary melanoma is usually thinner than the first, probably the result of increased clinical surveillance.²¹⁶¹ Furthermore, some overdiagnosis appears more likely to occur with second lesions.²¹⁶² Patients with three or more primary melanomas survive longer than anticipated.²¹⁶³

Patients with multiple primary lesions have a strong association with germline *CDKN2A* and *CDK4* mutations.^{2154,2162,2164,2165}

Special techniques to aid diagnosis

Morphologic assessment of H&E-stained sections from biopsy material remains the gold standard for the diagnosis of melanoma. There are many lesions – for example, dysplastic (atypical) nevi, Spitz nevi, special site nevi, and atypical nevi not otherwise specified – that share some but not all features with melanoma^{2166–2169} and lead to marked interobserver variability.^{2170,2171} For these borderline lesions, other techniques have been employed in order to improve diagnostic accuracy. These include surface microscopy using the dermatoscope (dermoscopy) and other noninvasive (pre-biopsy) techniques, special stains, AgNOR counts, electron microscopy for pre-melanosome/melanosome detection, immunohistochemistry, and newer molecular techniques.²¹⁷² Select techniques are discussed further.

Dermoscopy and other pre-biopsy (*in vivo*) techniques

Surface microscopy using the dermatoscope (**epiluminescence microscopy** (ELM)) has become widely used by clinicians in the assessment of pigmented lesions. It is a useful clinical tool for the discrimination of benign and malignant nevomelanocytic lesions.^{2173–2197} Dermoscopic features specific to certain lesions are covered under those entities. Dermoscopic criteria for biopsy include variations of the ABCDE clinical criteria along with assessment of pigment patterns and microanatomic structures.^{2198–2204} Consensus statements have been issued by the International Dermoscopy Society to help standardize terminology and methods.^{2205,2206} Dermoscopy increases diagnostic accuracy over clinical visual inspection by 5–30%.^{2207–2212} Its use is limited in the diagnosis of very early and mainly featureless melanomas.^{2213–2215} It has been suggested that both histopathological and dermoscopic evaluation be carried out on these featureless melanomas.^{2215,2216} Dermoscopy is good for the surveillance of patients at high risk for cutaneous melanoma.^{2217–2220} It can also be used short term to monitor suspicious lesions.^{2221,2222} It is particularly useful in the diagnosis of pigmented lesions on acral volar skin.^{2223,2224} If there are dermoscopic features of regression, the histopathological diagnosis is sometimes equivocal.²²²⁵ Dermoscopy can be used to guide the pathologist to areas of interest or suspicion.^{2226,2227} There is now good correlation between dermoscopic features and the corresponding histopathology.²²²⁸ The dermoscopy of

amelanotic/hypomelanotic melanomas can be difficult, but suspicious patterns have been elucidated.²²²⁹⁻²²³⁵ Nevus-associated melanoma is another area of difficulty, but atypical pigment networks and a regression pattern are useful criteria for this diagnosis.²²³⁶ The blue-white veil and irregular blue-gray dots (granularity) are two dermoscopic features of melanoma.^{2237,2238} Dermoscopy can accurately identify the vascular pigmentary and scarring changes of fully regressed melanoma, and it should be used in cases of metastatic melanoma of unknown origin.²²³⁹

Multispectral digital dermoscopy has evolved from classic dermoscopy.^{2186,2240-2244} Newer generations of devices can assess radiation intensity at a specific point and also evaluate the spatial, or microanatomic, changes in intensity and convert the data to a digital readout.²²⁴⁵ Monheit *et al.* reported a sensitivity of 98.3% ($n = 175$) for detecting melanoma using the computer-aided multispectral digital analysis system MelaFind®.²²⁴¹ The specificity was 9.9% on lesions biopsied to rule out melanoma, compared to 3.7% for clinicians.²²⁴¹ Similarly positive performance characteristics have been reported using other digital ELM devices, such as DermaScope®, EpiScope®, Nevoscope®, and MoleMax®.^{2242,2245,2246} **Confocal scanning laser microscopy (CSLM)** is another commercially available technology. CSLM is a noninvasive, high-resolution technology that can visualize superficial skin almost to the detail of histology.^{2247,2248} Excellent performance characteristics of CSLM have been reported: 90–95% sensitivity and 80–85% specificity.^{2245,2247-2250} Many of these devices have been approved by the U.S. Food and Drug Administration (FDA) for the assessment of clinically atypical cutaneous pigmented lesions and to aid in the decision to biopsy.²²⁵¹ Related technologies currently under investigation include Raman spectroscopy, infrared spectroscopy, infrared thermography, terahertz imaging, and optical coherence tomography.^{2245,2246} Some of these may become available for clinical use in the near future. Dermoscopy, either manual or digital, and other *in vivo* techniques are intended to enhance, not replace, biopsy practices.

Tape-stripping is another method used to extract diagnostic material and potentially avoid biopsy. By applying tape to the skin surface of clinically atypical pigmented lesions and stripping off the superficial components, a diagnosis of melanoma can be established by cytologic examination²²⁵² or, more recently, by evaluating the gene expression profile via extracted RNA.²²⁵³ One study, using a commercially available tape-stripping gene expression assay for melanoma, reported a sensitivity of 100% and specificity of 88% compared to histologic evaluation.²²⁵³ These initial data are promising but still early, and the true utility of tape-stripping in the clinical setting will likely be determined during the next few years.

Special stains and immunohistochemistry

Special stains and immunohistochemical analysis are effective tools to determine melanocytic differentiation, but they are less effective at distinguishing melanoma from nevus.²²⁵⁴ Masson–Fontana, PAS, Schmorl's, and modified Warthin–Starry stains can detect melanin, but their use for diagnosing melanoma is primarily historical.²²⁵⁵⁻²²⁵⁷ These stains have been replaced by more sophisticated immunohistochemical (immunoperoxidase) techniques, which utilize a more specific antibody–antigen interaction. S100, SOX-10, MART-1, gp100, tyrosinase, and MiTF are all effective melanocyte-specific antigens and have roles in specific diagnostic settings.²²⁵⁸⁻²²⁶¹ Some of these have already been discussed in the context of specific entities. There is a whole body of literature dedicated to evaluating antibodies directed to melanocytic lesions with a hope to distinguish melanoma from nevus. For now, however, the search for an effective melanoma-specific antigen continues.

S100 (name derived from 'saturated at 100%') and **SOX-10** (SRY-related HMG-box) protein are the most sensitive immunohistochemical markers for melanoma, positive in 90–99% of cases (average, ~95%), and have similar expression profiles.^{2254,2258,2262-2266} S100 protein is not a single protein but, rather, a family of more than 20 acidic

calcium-binding proteins that are important in intracellular calcium metabolism.²²⁶⁷ SOX-10 is a transcription factor with an important role in neural crest development. S100 has nuclear and cytoplasmic expression, whereas SOX-10 has nuclear expression only. Both proteins are present in neural crest-derived entities and are observed in melanoma, nevi, clear cell sarcoma, benign and malignant peripheral nerve sheath tumors, and myoepithelial cells.^{2265,2266,2268} S100 protein is also found in subsets of synovial sarcoma, Ewing sarcoma, rhabdomyosarcoma, and chondrosarcoma, as well as Langerhans cells, other dendritic cells, and adipocytes.²²⁶⁵ Because S100 is expressed in this slightly expanded group of tumors, the specificity of SOX-10 for melanoma is slightly higher than the reported 75–87% specificity for S100.^{2263,2264} S100 and SOX-10 are the most reliable of the melanocytic antigens for diagnosing desmoplastic melanoma.^{2269,2270} Melanomas negative for S100 and SOX-10 are occasionally encountered and may rarely express other melanocytic antigens, but these tumors remain a diagnostic challenge.²²⁷¹ Different members of the S100 family of proteins, including S100A1, S100A2, S100A4, S100A6, and S100B, have been evaluated by immunohistochemistry on melanomas and both benign and malignant peripheral nerve sheath tumors and show only slight variations in expression patterns.^{2270,2272} S100A2 protein is upregulated in atypical keratinocytes in pigmented actinic keratoses.²²⁷³

MART-1 (melanoma antigen recognized by T cells 1) and **gp100** (pre-melanosome protein (PMEL)) are other commonly used melanocytic markers.²²⁵⁸⁻²²⁶¹ Many antibody clones, including A-103, are available for detecting MART-1 (**melan-A**). MART-1 is a melanocytic differentiation antigen with expression in skin, retina, and melanocyte cell lines and within melanocytic proliferations such as nevi and melanoma.²²⁷⁴ gp100 is a premelanosome protein that is recognized by the antibody **HMB-45**. HMB-45 appears to stain melanosomes early in their formation but not late (stage IV) melanosomes.²²⁷⁵ gp100 expression is observed in stimulated melanocytes such as junctional melanocytes in nevi, dermal nevus cells in pigmented lesions removed from some patients with HIV infection,²²⁷⁶ the cells in deep penetrating nevi, some cells in the papillary dermis in atypical (dysplastic) nevi, melanocytes in blue nevi, some cells in Spitz nevi, and subsets of melanoma.^{2259-2261,2277-2279} MART-1 and gp100 expression may be observed in angiomyolipomas, PEComas, lymphangioleiomyomatosis, and clear cell sugar tumors of the lung.²²⁸⁰ MART-1 and gp100 markers are less sensitive than S100 and SOX-10 for melanoma.²²⁶³ One study of 322 melanomas, including all histologic subtypes, reported sensitivities of 73.3 and 63.0% for MART-1 and gp100, respectively.²²⁶³ Although there are variations in reported sensitivities/specificities among studies, MART-1 is consistently more sensitive than gp100/HMB-45, and both are more specific than S100 protein immunohistochemistry.²²⁸¹⁻²²⁸⁶ MART-1 is diffusely expressed in melanomas, whereas gp100 has patchy expression (not stratified from top to bottom as in most nevi).¹⁹³⁴ Neither are expressed in most desmoplastic melanomas.^{2264,2287} A spindle cell melanocytic lesion that does not express MART-1 is more likely to be a melanoma than a nevus.¹⁹³⁹ MART-1 immunohistochemistry has been proposed as a valuable method for the identification of neoplastic cells in the lymphocytic infiltrate associated with thin melanomas²²⁸⁸ or to more clearly define the spread of lentigo maligna. However, MART-1 expression on sun-damaged skin may show an increased density of melanocytes, potentially leading to overdiagnosis of lentigo maligna.²²⁸⁹ Several studies have noted MART-1 expression within keratinocytes, in the context of inflammation and/or keratinocytic dysplasia, as a potential diagnostic pitfall.²²⁹⁰⁻²²⁹² Others have failed to confirm these findings.^{2293,2294} Rapid gp100²²⁹⁵ and MART-1²²⁹⁶ immunohistochemistry have been used to aid in the interpretation of frozen sections during Mohs micrographic surgery in the treatment of melanoma.

Tyrosinase, **NKI-C3** (CD63), and **MiTF** (microphthalmia transcription factor) are expressed in most benign nevi and melanomas, with the exception of desmoplastic melanomas.^{2297,2298} Antibodies to tyrosinase are commonly mixed with other antibodies in melanocyte-specific

immunohistochemical cocktails, especially when assessing lymph nodes for micrometastases.^{2299,2300} NKI-C3 is expressed in most melanomas²²⁸⁶ but lacks specificity. Expression can be observed, for example, in cellular neurothekeomas, fibrohistiocytic tumors (xanthogranulomas, cellular fibrous histiocytomas, etc.), and epithelial tumors.²³⁰¹⁻²³⁰³ MiTF and SOX-10 are nuclear antigens, and immunohistochemical analysis has proven useful for differentiating lentigo maligna from pigmented actinic keratoses.^{2304,2305} MiTF immunohistochemistry is an option for diagnosing metastatic melanoma when all other melanocytic markers are negative.²³⁰⁶ MiTF lacks the specificity of MART-1, gp100, and tyrosinase because it also is expressed in hematolymphoid populations, fibroblasts, Schwann cells, and smooth muscle.¹⁹³⁹ Many other immunohistochemical markers have been reported as expressed in subsets of melanoma ± nevi. These may be observed in unique settings but have limited diagnostic value. Examples include keratins,^{2307,2308} vimentin,²³⁰⁹ neuron-specific enolase (NSE),²³¹⁰ 3G5,²³¹¹ WT-1,^{2312,2313} CD34,¹⁹⁴⁰ MAGE-1,^{2314,2315} bcl-2,²³¹⁶⁻²³²⁰ CD44,²³²¹⁻²³²⁸ and PCNA.^{555,2329-2332}

Other groups of antibodies/antigens have been tested to discriminate melanoma from nevi, but with little success. Many of these generate initial excitement with promising data when evaluating unequivocal melanomas and nevi, but they lose diagnostic power in the subset of atypical lesions, which are the lesions most in need of ancillary studies. The **Ki-67** antigen, a marker of cellular proliferation, is expressed variably in melanomas but not nevi.^{1939,2333,2334} It can be identified in paraffin sections using the monoclonal antibody MIB-1, among others. Common nevi and atypical (dysplastic) nevi express Ki-67 in less than 1% of cells. Spitz nevi, blue nevi, and related nevi can have variable expression levels. Melanocytic lesions with greater than 10% of cells positive for Ki-67, or with random or deep positive cells, are very concerning for melanoma, suggesting a possible role for its use in borderline lesions.^{556,2335,2336} Thick melanomas (>4 mm) with high Ki-67 expression have a poor prognosis,²³³⁷⁻²³³⁹ but Ki-67 expression does not appear to have independent prognostic significance for most melanomas.²³⁴⁰⁻²³⁴³ More recently discovered **PHH3** and **MPM-2** (mitotic protein monoclonal 2) are used as a surrogate for mitotic figures and are more closely related to mitotic count than is Ki-67. Increased PHH3 predicts decreased progression-free survival of melanoma patients but currently offers little advantage over standard mitotic counts.²³⁴⁴

Neuropilin-2 recently was used to help distinguish Spitz nevi (26% positive) from Spitzoid melanomas (100% positive) in one study.⁵⁶⁵ **CD99** is expressed in approximately 60% of melanomas²³⁴⁵ and also may have a role in differentiating Spitzoid melanomas from Spitz nevi.⁵⁶⁴ Tumor suppressor **p16**, a splice product of *CDKN2A*, has been of great interest as a diagnostic marker, but so far, its ability to distinguish melanoma from nevus has been disappointing.^{2062,2346} The tumor suppressor protein **p53** is expressed in up to 50% of melanomas but not in benign nevi, although occasional foci of weak nuclear immunoreactivity can be seen in some dysplastic (atypical) nevi and Spitz nevi.²³⁴⁷⁻²³⁴⁹ p53 was strongly expressed in melanomas with a poor prognosis in one study,²³⁴⁷ but it was associated with improved survival in another.²³⁵⁰ **MCM** (minichromosome maintenance protein), a polypeptide involved in DNA replication, is expressed in approximately 40% of melanomas but in only 1% of nevi.²³⁵¹ **p75** (NGFR) has been reported as a highly sensitive marker for desmoplastic melanoma,^{1918,1935,1942,2352} but a more recent study found that it was not reliable for distinguishing desmoplastic melanoma from scar, one of its main histologic mimics.¹⁹⁴² **Survivin**,^{2353,2354} **galectin-3**,²³⁵⁵⁻²³⁵⁸ **COX-2** (cyclooxygenase-2),²³⁵⁹⁻²³⁶¹ and **claudin-1**²³⁶² are examples of other immunohistochemical markers with a possible role in melanoma tumor progression and/or prognosis, but a clear diagnostic utility has yet to be realized.

Immunohistochemistry recently has been evaluated as a surrogate for specific molecular events and, in some cases, to predict responses to therapy. **BAP1**-inactivating mutations are effectively identified using immunohistochemistry (see p. 898).¹⁴⁹⁵ Antibodies specific for **B-Raf**^{V600E} (**VE1** antibody) are effective at detecting tumor cells

harboring this specific mutation, with good interobserver reproducibility.^{2363,2364} Although this has no current diagnostic value for melanocytic lesions, and questions remain regarding its sensitivity and specificity for specific mutations,²³⁶⁵ it may be helpful for determining patient eligibility for targeted therapy in some settings. Regarding **Kit** (CD117), there is currently no clear role for immunohistochemistry in melanoma. Loss of Kit expression has been reported with melanoma progression, specifically invasion and metastasis.²³⁶⁶ In addition, expression of Kit by immunohistochemistry does not correlate with mutational/amplification status nor efficacy of Kit inhibitor therapy.^{1534,2367}

Other

The measurement of silver-positive nucleolar organizer regions (AgNOR count) in a representative number of tumor cells has been used to assess malignant potential and prognosis in borderline melanocytic lesions, melanomas, and other cancers.^{562,2368-2375} The mean AgNOR count for melanoma cells is significantly higher than that for benign nevus cells, although some overlap occurs, particularly with Spitz nevi and atypical (dysplastic) nevi.^{562,2376,2377} An AgNOR count of more than 2.5 per cell is very suggestive of a malignant melanoma.^{1144-1147,2376,2378} AgNOR assessment is included here primarily for historical purposes because it is not widely implemented in dermatopathology and has largely been replaced by newer molecular methods.

Electron microscopy has played an important historical role in the ultrastructural characterization of melanoma.^{2379,2380} It is no longer used with any significant frequency but still may play a role when confronted with a poorly differentiated neoplasm or in other select settings.²³⁸¹ Stage II melanosomes are considered the hallmark of melanoma and melanin synthesis. They are found rarely in other tumors.²³⁸² Care must be taken to avoid mistaking myelin figures for aberrant melanosomes. The melanosomes in the atypical melanocytes of lentigo maligna melanoma are usually ellipsoidal and resemble those of normal melanocytes, unlike the spheroidal and abnormal appearance of the melanosomes in superficial spreading and nodular melanomas.²³⁸⁰ The cells in a desmoplastic melanoma have abundant rough endoplasmic reticulum and sometimes intracytoplasmic collagen and macular desmosomes.^{1905,2383} In these tumors, ultrastructural fibroblastic and Schwannian differentiation have been observed.^{1906,2384} Non-membrane-bound melanin granules and pre-melanosomes have been noted in some cases of desmoplastic melanoma,¹⁹⁰⁵ although they have been specifically excluded in others.^{2382,2384} The most widely accepted view is that the desmoplastic component is derived from melanocytes that have undergone adaptive fibroplasia,¹⁹⁰⁵ although contrary views favor a fibroblastic stromal response¹⁷⁸¹ or neurosarcomatous differentiation.²³⁸⁴

Molecular techniques

Comparative genomic hybridization (CGH) is a very powerful technique that can detect and localize genome-wide variations in whole or partial chromosomal copy number.²³⁸⁵ Detection of these aberrations can be used for diagnostic purposes. The general principle behind CGH is to compare the tumor genome with a background normal genome and identify differences, such as gains and losses of genetic material, between tumor and normal cells. Traditional CGH using metaphase spreads of chromosomes largely has been replaced by array platforms, or **aCGH**, which can identify aberrations as small as 200 base pairs.²³⁸⁶ Melanomas, as with most malignancies, have a higher number of chromosomal aberrations than their nonmalignant counterparts, and these aberrations are reproducible.^{2387,2388} Using CGH analysis on 132 melanomas and 54 nevi, Bastian *et al.* showed 96% of melanomas had aberrations. The most common of these were losses in 9p (64%), 9q (36%), and 10q (36%) and gains in 6p (37%), 1q (33%), 7p (32%), and 7q (32%).²³⁸⁸ Aberrations in nevi appear restricted to subgroups of Spitz nevi and consist of 11p gains.^{490,491,2388,2389} Melanomas also may have gains in 11p, but this occurs in the context of

multiple other chromosomal abnormalities.²³⁸⁹ Partial gains and losses appear much more commonly in melanomas than with nevi, possibly reflecting different mechanisms behind the development of chromosomal aberrations.

CGH has been shown to help distinguish Spitz nevi from melanoma, blue nevi from blue nevi-like malignancies,⁹³⁹ and melanoma arising in a congenital nevus from benign proliferative nodules,²³⁹⁰ among other applications. Although the potential power of CGH is clear, in its current form, it has some limitations preventing its widespread use as a melanoma diagnostic assay. CGH requires high tumor purity (the chromosomal aberration must be present in at least 30–50% of the cells analyzed) for optimal performance. This may prevent use of CGH on biopsies with only small foci of tumor, superficially invasive tumors, heavily inflamed tumors, and genetically heterogeneous tumors. Another limitation is interpretation of the data. CGH can evaluate the entire genome, and although this is one of its main attractions, identifying melanoma-specific and/or biologically relevant variations in copy number is a new bioinformatics challenge.

Fluorescence in situ hybridization (FISH) uses fluorescently labeled segments (probes) of DNA that are designed to hybridize to targets in the genome. Like CGH, FISH exploits the principle that melanoma, and not nevi, often develop chromosomal copy number changes. Because normal human cells are diploid, a normal cell will have two signals per probe. Changes in probe target copy number are easily detectable (Fig. 32.48). FISH has been used for decades in the research setting for the evaluation of melanoma.^{2391,2392} With the recent discovery of probe sets able to effectively discriminate nevi from melanoma,^{2393,2394} commercial tests are now available. Early concerns regarding the sensitivity and specificity of the melanoma FISH assay, including false-positive results in Spitz nevi due to tetraploidy,^{569,570} have been addressed in more recent probe sets and revisions to interpretation criteria.²⁴⁹⁴ The FISH probe set published in 2012 by Gerami *et al.* targets *CDKN2A* (9p21), *MYC* (8q24), *RREB1* (6p25), and *CCND1* (11q13). Melanomas are associated with any of the following: homozygous loss of 9p21, gains of 8q24, gains of 6p25, and gains of 11q13.²³⁹⁴

Figure 32.48 Evaluation for melanoma by FISH. Paraffin-embedded tissue FISH (PET-FISH) can be used to assess histologically ambiguous lesions using probes to *RREB1* (red), *CCND1* (green), *MYC* (aqua), and *CDKN2A/p16* (gold). Two signals for each probe are observed in normal cells (bottom middle cell). Melanomas often have changes in chromosome copy numbers. In this case, the absence of *CDKN2A/p16* signals (homozygous loss) is suggestive of melanoma (all other cells in field).

Since its inception, the melanoma FISH assay has been used in a variety of diagnostic settings, including distinguishing atypical (including Spitzoid) nevi from melanoma,^{2393–2396} conjunctival nevi from melanoma,²³⁹⁷ epithelioid blue nevi from blue nevi-like malignancies,⁹¹⁹ mitotically active benign nevi from nevoid melanoma,²³⁹⁸ atypical (dysplastic) nevi from superficial spreading melanoma,²³⁹⁹ and others.^{2395,2400–2402} The sensitivity of the FISH assay appears to vary based on melanoma subtype, ranging from almost 100% with acral melanomas to 81% for superficial spreading melanoma and 50% for desmoplastic melanoma.^{2403,2404} The impact of histologic type on performance parameters using newer generation probe sets is still under investigation. Some chromosomal abnormalities are becoming more clearly associated or disassociated with specific histologic subtypes (e.g., 8q24 gains associated with amelanotic and nevoid melanoma and not with Spitzoid lesions).²⁴⁰⁵ Also, some chromosomal abnormalities are emerging as more important in certain diagnostic settings (e.g., homozygous loss of 9p21 more meaningful than 6q23 deletion in Spitzoid tumors, and 11q13 gains are very significant in any lesion). These interpretative nuances have added another layer of sophistication to FISH as a diagnostic assay. In addition to its diagnostic applications, FISH also has been used to guide surgical management by assessing surgical margins for histologically undetectable tumor and field cells,²⁴⁰⁶ in a form of staging by distinguishing capsular or intranodal nevi from lymph node metastases,²⁴⁰⁷ and as a potential prognostic marker because *CCND1*, *MYC*, and topoisomerase I amplification all have been associated with poor prognosis.^{2408–2410}

Mutational analysis is now an important component in the evaluation and management of the melanoma patient. The recent increase in the understanding of signaling pathways in melanoma¹⁴⁹⁸ was followed by the development of assays to detect mutations in key molecules within these pathways. These assays offer promise to improve diagnostic accuracy, better predict prognosis, and guide therapy, collectively providing a new level of personalized medicine. The mutational status of key melanoma signaling molecules can be determined by a variety of different molecular methods, including but not limited to Sanger 2X bidirectional sequencing, allele-specific PCR, TaqMan® real-time PCR, pyrosequencing, PCR with mass spectroscopy, and, more recently, Next-Generation (massively parallel, high-throughput) sequencing.²¹⁷² All of these assays require DNA extraction from a paraffin block or slides, usually with the assistance of a pathologist/dermatopathologist to identify areas with high tumor purity.²¹⁷²

To date, mutational analysis is not used for *diagnostic* purposes in the context of melanoma. The primary reasons for this include: the same mutations are observed in both melanomas and nevi; the mutation is observed in malignancies other than melanoma; and/or the molecular information does not add anything to standard clinical, morphological, and immunohistochemical diagnostic criteria. For example, the specific *BRAF* V600E (T → A at the second position in codon 600 resulting in Val600Glu) mutation is mutated in approximately half of all melanomas.¹⁴⁹⁸ This exact mutation is observed in many other malignancies, including tumors of the thyroid, lung, gastrointestinal tract, genitourinary system, and hematopoietic system,¹⁵¹⁶ as well as in up to 82% of benign nevi, including common acquired nevi, nevi with architectural disorder (dysplastic nevi), small and medium-sized congenital nevi and congenital-like nevi, and, to a lesser extent, blue nevi.^{1522,1523} Because of its apparent inability to distinguish malignant from benign or melanoma from other malignancies, *BRAF* V600E mutational analysis has no current clear role for diagnosis. Similarly, the same *NRAS* and *GNAQ/11* mutations observed in melanoma are also observed in subsets of nevi (primarily blue nevi for *GNAQ/11* mutations and giant congenital nevi for *NRAS* mutations).^{725,1547} *HRAS* mutations and/or amplifications are seen in 10–29% of Spitz nevi but are not typical for melanoma, suggesting a possible diagnostic application.⁴⁹¹ Mutational analysis of other genes commonly mutated in melanoma – for example, *KIT*, *TERT*, *MITF*, *PIK3CA*, *AKT1/3*, and *CDKN2A* – has no clear

current diagnostic value. With the emergence of newly defined genetic subsets of melanoma (e.g., *BAP1*-mutated tumors), which may have genetically driven differences in malignant potential, mutational analyses may play a more prominent role in diagnosis (and reclassification) of melanomas in the future.

Although mutational analysis for diagnostic purposes has yet to be realized, it has an unequivocal role in the selection of targeted therapy and has revolutionized the approach to the advanced melanoma patient. The first evidence for this came from the results of the *BRAF* in Melanoma (BRIM) trials.^{1201,2411} Advanced-stage melanoma patients harboring the *BRAF* V600E mutation within their tumors, treated with the B-Raf^{V600E} inhibitor vemurafenib, had a clear survival advantage over the dacarbazine control group.¹²⁰¹ *BRAF* mutational status predicts a therapeutic response to inhibitor therapy, and testing for *BRAF* V600E is now commonplace for the advanced-stage melanoma patient to determine therapeutic eligibility. In addition to V600E (>90% of V600 mutations), there are other activating mutations at V600, including V600K (8%), V600R (1%), V600E(2) (V600E by the complex V → E mutation bp.1799/1800TG→AA) (0.5%), and a mix of others (<1%); however, less is known about the biology of these alternate mutations and their responses to individual B-Raf inhibitor therapies.^{1509,2412,2413} *NRAS* mutations occur in 15–20% of melanomas, with Q61 the most commonly mutated residue.^{1441,1499,1501,1502,1509,2413} Mutational analysis of *NRAS* is less commonly performed because no effective N-Ras inhibitor therapy is available. Determining *NRAS* mutation status may be important for identifying individuals who may respond well to high-dose IL-2,¹⁵⁰⁸ those who may respond negatively to B-Raf inhibitor therapy (through paradoxical activation of the MAP kinase pathway),²⁴¹⁴ or those who develop *NRAS*-mediated resistance to B-Raf inhibitor therapy.^{2415,2416} As recognition that subtypes of melanoma have alterations in *KIT* and may respond to Kit-inhibitor therapy, the demand for *KIT* testing has increased.^{1536,2417} The association between *KIT* mutations and decreased overall survival provides further rationale for testing.¹⁵³⁷ Due to the high prevalence of *KIT* mutations in acral lentiginous melanoma, primary mucosal melanoma, and melanoma of chronically sun-damaged skin, *KIT* testing may be considered for advanced-stage melanoma patients with these types of tumors. Kit-inhibitor therapy appears to be more efficacious for melanomas with activating (not silent) *KIT* mutations and not with amplifications, underscoring the importance of testing and appropriate patient selection prior to therapy.

Next-generation (high throughput) **sequencing** is becoming a popular method for simultaneously assessing multiple genes. It may eventually replace other mutational assays as well as CGH.

Gene expression profiling is another molecular method actively being pursued as a diagnostic tool. Its current role, however, primarily has been limited to prognostication (see below).

Prognostic factors in melanoma and survival

The prognosis of the melanoma patient currently is best determined by the patient's clinical and pathologic stage. These stages have been defined by an international effort based on survival data and published in their most recent form in the 2011 seventh edition of the *AJCC Cancer Staging Manual*.^{2418,2419} The clinical stage is dependent on microstaging of the primary tumor along with clinical, radiographic, and laboratory evidence for metastatic disease. The pathologic stage is determined by microstaging the primary tumor and (if applicable) by pathologic evaluation of a sentinel lymph node and/or completion regional lymphadenectomy.

These staging systems utilize multivariate analyses to identify specific parameters with independent prognostic value. In general, the histomorphologic prognostic parameters used in staging have good interobserver reproducibility.^{2420–2422} These parameters should be included in all synoptic pathology reports (see p. 879). Many other parameters (e.g., radial vs. vertical phase) have an association with

Table 32.6 Prognostic features of melanoma

Pathological
Distant metastases (A)
Nodal (including clinically occult) disease (A)
In-transit or microsatellite deposits (A)
Increasing Breslow depth (A)
Ulceration (A)
Increasing mitotic rate/mitotic index (A)
Increased nuclear volume (C/A)
Hemangiolymphatic invasion (C/A)
Clark level (C)
Histological subtype (C)
Lymphocytic infiltrate (C/F)
Regression (C)
Coexisting nevus (C)

'Class 2' expression profiles (ocular/cutaneous melanoma) (A)
Other biomarkers (see text)

A, adverse; C, conflicting reports or currently not clearly independently predictive; F, favorable.

prognosis but likely are linked to another factor, such as tumor depth or ulceration, and offer no additional (independent) prognostic value. Other parameters currently are being evaluated. Various prognostic features, with their significance, are listed in **Table 32.6**.

Survival data are dependent on stage.^{2418,2419} For example, the 5-year survival for stage IA disease is 97%, whereas the 5-year survival for stage IV (distant metastatic) disease is less than 30%.^{2418,2419} Similar data have been reported in various specific populations worldwide (specifically, western Europe, Australia, and North America).^{1162,1166,1169,1171,1190,2423–2426} In general, during the past several decades, survival curves have been fairly flat (see p. 866). Hazard rate analyses suggest that the peak hazard rate for death in clinical stage I cutaneous melanoma is the 48th month of follow-up, and that after 120 months the risk of dying from melanoma is virtually zero.²⁴²⁷ With respect to recurrences, patients with thick melanomas have a marked reduction in future risk of recurrence with time.²⁴²⁸ In other words, their greatest risk is in the first few years after removal of their thick lesion. Overall, 80% of recurrences occur within the first 3 years.²⁴²⁹ Although uncommon, ultra-late recurrences (beyond 40 years) are recorded.^{1574,1575} In melanoma patients disease-free at 10 years post diagnosis (of invasive melanoma), approximately 7% will have metastases at 15 years and 11% at 20 years.²⁴³⁰ The probability of cure increases with progressively longer recurrence-free survival.²⁴³¹

Population recurrence and survival data can be misleading for patients with melanoma.²⁴³² Websites are available as educational tools for patients and caregivers, translating the staging data into a meaningful form for the individual.^{2433,2434}

Lymph node and distant metastases

The sentinel lymph nodes in the lymphatic basins are the first nodes to be involved in metastatic disease; therefore, evaluation for tumor in this lymph node is an effective mechanism for determining prognosis.²⁴³⁵ Their involvement, including the presence of so-called ‘occult metastases’, has adverse prognostic significance and is the single most important predictor of survival outside of distant metastases.^{2418,2419,2436} Prognosis is dependent on the number of involved lymph nodes and whether the deposits are microscopic (clinically occult) or macroscopic. A single positive lymph node (N1), however defined, is stage III, with a 5-year survival of 40–70%.^{2418,2419} A lymph node is considered positive if there are satellite or in-transit metastases or if there is pathologic evidence of melanoma in the lymph node itself, as determined by routine H&E sections or immunohistochemistry, with melanocyte-specific antibodies such as melan-A or HMB-45. There is no tumor burden cutoff defining a positive lymph node in melanoma. Detection of tumor by molecular techniques (PCR and RT-PCR), however, currently does not define a positive node because these assays may be overly sensitive and lack specificity.^{2437–2441}

Stage IV disease has a uniformly poor prognosis, with a 1-year survival of 40–60%.^{2418,2419} There are slight variations in survival based on the anatomic site of the metastasis: skin/subcutis/distant lymph nodes (M1a), lung (M1b), and all other distant sites or elevated lactate dehydrogenase (M1c).^{2418,2419,2442} The detection of circulating melanocytes by molecular methods (PCR, RT-PCR) is also an adverse prognostic finding,²⁴⁴³ but this strategy is not widely implemented to assess prognosis.

Satellite deposits and in-transit metastases

The presence of tumor deposits separate from the main tumor mass has an adverse influence on prognosis.^{2444–2449} Microsatellites (defined as a tumor focus >0.05 mm in diameter separated from the main tumor mass by at least 0.3 mm), satellite nodules, and in-transit metastases have a similar impact on survival and are considered stage III disease in the most recent AJCC staging system.^{2418,2419} The presence of microsatellites has been shown to be a better indicator of occult regional lymph node metastases in clinical stage I melanoma than the tumor thickness.²⁴⁵⁰

Tumor thickness

As has held constant throughout the AJCC editions, the pathologic stage (in node-negative disease), and therefore prognosis, is largely determined by the depth of tumor invasion, specifically the **Breslow depth**.^{2418,2419,2451–2453} The Breslow depth is measured from the top of the granular layer (undersurface of the stratum corneum) to the deepest tumor cell. This depth is a reproducible measurement, although some interobserver variation occurs.²⁴⁵⁴ It can be accurately measured on deep shave biopsies and by 75-MHz ultrasonography.^{2455,2456} Breslow originally divided melanomas into five groups based on tumor depth: ≤0.75 mm (stage I), 0.75–1.5 mm (stage II), 1.51–2.25 mm (stage III), 2.25–3.0 mm (stage IV), and >3.0 mm (stage V).²⁴⁵¹ In the AJCC 2011 seventh edition, the pathologic stages are divided by Breslow depth as follows:^{2418,2419}

- pT1: ≤1.0 mm
- pT2: 1.01–2.0 mm
- pT3: 2.01–4.0 mm
- pT4: >4.0 mm.

The 5-year survival for stage pT1a is 97% and worsens with increased tumor thickness: 91% for T2a, 79% for T3a, and 71% for T4a.^{2418,2419}

The prognosis of patients with a melanoma less than 0.5 mm in thickness at diagnosis is excellent, with 5-year survival rates approaching 100%.^{2419,2457} Some centers continue to use ≤0.75 mm as a cutoff for thin melanomas (and to determine eligibility for sentinel lymph node biopsy). Prognosis likely is related to thickness along a continuum.²⁴⁵⁸ Thicker tumors may, in some instances, be a consequence of inherently more aggressive tumors rather than a reflection of delays in diagnosis.^{2459–2462} Thickness is not an infallible predictor of prognosis for an individual lesion.²⁴⁶³ For example, patients with desmoplastic melanoma present, on average, with thicker tumors and therefore higher tumor stages than patients with other histologic subtypes. This would predict a worse prognosis, but patients with pure desmoplastic melanomas rarely develop regional metastases and survival is better than would be predicted by Breslow depth alone.^{2464,2465} Conversely, prognosis may be worse than predicted by Breslow depth because sequential serial sectioning increases the Breslow thickness in almost 50% of cases.^{2466,2467} Tumor cross-sectional area²⁴⁶⁸ and tumor volume²⁴⁶⁹ also predict prognosis but have limited prognostic value over standard Breslow depth and are not routinely measured.

The **Clark level**, which uses anatomic barriers instead of raw measurements for tumor depth, is often reported but no longer required for staging.^{1577,2418,2419}

Five anatomical levels are recognized:¹⁵⁷⁷

- I: Confined to the epidermis (*in situ* melanoma)
- II: Invasion of the papillary dermis
- III: Invasion to the papillary–reticular dermal interface
- IV: Invasion into the reticular dermis
- V: Invasion into subcutaneous fat.

Most authors now agree that the prognostic significance of the Clark level is derived from its secondary correlation with tumor thickness.^{2470,2471}

Ulceration

Ulceration is a strong negative prognostic parameter because it upstages the pathologic stage a → b (1a → 1b, 2a → 2b, etc.).^{2418,2419,2472–2474} This effectively upstages the clinical stage (IA → IB, IB → IIA, etc.) because the presence of ulceration shifts the survival curve to superimpose the curve corresponding to the next highest Breslow category without ulceration (e.g., T1b = T2a).^{2418,2419} The negative impact is magnified when the ulceration exceeds 3 mm in width.²⁴⁷⁵ There is a statistically significant relationship between the increasing percentage of tumor ulceration and both sentinel lymph node status and overall survival.²⁴⁷⁵ Ulcerated melanomas also have significantly more mitoses.²⁴⁷⁶ Iatrogenic ulceration or other trauma has no prognostic significance.²⁴⁷⁷

Mitotic rate

The mitotic rate has important prognostic significance.^{2418,2419,2478,2479} A rate greater than 6/mm² was initially thought to be the significant level, but Azzola *et al.* found that there were no significant survival differences for the stepwise increases in mitotic activity beyond 1 mitosis/mm².²⁴⁸⁰ Although the independent prognostic value of mitotic rate has been disputed,²⁴⁸¹ the presence of a single mitosis is now considered significant and upstages thin melanomas pT1a → pT1b, similar to ulceration.^{2418,2419} Mitotic rate does not have clear independent prognostic value for thicker melanomas, and in these circumstances, does not impact the stage.^{2418,2419,2481} The product of the thickness in millimeters and the number of mitoses per square millimeter (the prognostic index) may give prognostic information,^{2482,2483} but this is not widely used.

Histological subtype

It is generally agreed upon that there are no survival differences among superficial spreading, nodular, and acral lentiginous melanomas when these are corrected for thickness.^{1726,1968,2484,2485} Several exceptions have

been reported, but these data are not firm.^{2486–2488} McGovern *et al.* reported that lentigo maligna melanoma, particularly in women, has a more favorable prognosis, independent of thickness.²⁴⁸⁶ A study from Germany found that the prognosis for nodular melanomas is slightly worse than that for non-nodular melanomas, independent of thickness.²⁴⁸⁸ Desmoplastic melanoma, when it is ‘pure’, appears to have a favorable prognosis compared with other histologic types of the same depth.^{2464,2465}

Lymphocytic infiltration

Although some investigators have found no association between prognosis and lymphocytic infiltration of the lesion,²⁴⁸⁹ Clark’s group found that tumor-infiltrating lymphocytes, particularly when ‘brisk’, were a favorable feature.²⁴⁹⁰ A study since that time found that a high ratio, when comparing the width of the lymphocytic infiltrate to the tumor width, correlated with improved survival.²⁴⁹¹ The gradual increase in tumor infiltrating lymphocytes during melanoma tumorigenesis may reflect increased antigenicity of the tumor cells.²⁴⁹² Some of these cells are regulatory T cells (T_{regs}). If they exert their regulatory capabilities, they may be responsible for the induction of immunotolerance, favoring melanoma progression.^{2493,2494} These regulatory T cells bear the transcription factor FOXP3. The lymphocytes are mostly cytotoxic (CD8⁺) T cells,²⁴⁹⁵ the survival is better in the high-density (brisk) group.²⁴⁹⁶ A recent study suggested that the melanophage may have an anti-tumor role in some melanomas.²⁴⁹⁷ Interobserver agreement in assessing lymphocytic infiltration is good.²⁴⁹⁸

Coexisting nevus

The prognostic significance of a coexisting intradermal nevus has been controversial.^{347,2499} Nevi have been found in approximately one-fourth to one-third of all melanomas, depending on the diligence with which a search is made and the criteria used for accepting a nevus.^{1115,1348} Some authors have suggested that a coexisting nevus may be associated with a more favorable prognosis,^{715,2500} but this has not been confirmed when the melanoma is controlled for tumor thickness.⁷¹⁷

Other histological features

Other histologic features have been evaluated for predicting aggressive tumor behavior and prognosis, but these data are limited and further evaluation using multivariate analysis is required to establish their independent prognostic value. Examples of features associated with an adverse prognosis include: increased nuclear volume and deviation from diploidy,^{2501–2505} hemangiolymphatic invasion,^{2506,2507} increased microvessel density at the tumor edge,²⁵⁰⁸ the presence of plasma cells in the primary lesion,^{2509,2510} lack of para-tumoral epidermal hyperplasia (in thick melanomas),²⁵¹¹ and an infiltrative deep margin (as opposed to pushing border).²⁵¹²

Clinical features with prognostic significance

Various clinical aspects have been studied for prognostic significance. It is well-established that *females* with clinical stage I and stage II melanoma have superior survival rates to males.^{2512–2517} This may result from the occurrence of lesions in prognostically more favorable sites than in males (lower extremities rather than the trunk) and/or the presence of thinner tumors at the time of removal.^{2518,2519} This enhanced survival does not appear to apply to stage IV disease.²⁵²⁰

Another clinical parameter with prognostic significance is *age*. Elderly patients tend to have lesions with adverse prognostic features, such as increased thickness and ulceration, therefore raising the question of the role of age as an independent prognostic parameter.^{2517,2521–2524} This increased thickness may be the consequence of inherently more aggressive tumors in the elderly. Melanomas in young children appear to have a better prognosis than those in older children and adults.^{2525,2526} This finding, in part, may be due to overdiagnosis of biologically irrelevant lesions in young children.^{2527,2528}

In some studies, the *anatomic site* has been shown to be a prognostic variable.^{2529–2531} High-risk sites include the so-called ‘BANS areas’ of the body – B (back), A (posterior upper arm), N (posterior neck), S (scalp) – and the feet and genitalia.^{2445,2529,2532} The thorax (including the back) has been identified in one study as being a prognostically adverse region.²⁵³¹ One study has shown that the survival of patients with melanoma of the lower extremity decreased with distance from the trunk.²⁵³³ Other studies have been unable to confirm a site-dependent difference in mortality for the BANS area,^{2534,2535} except for melanomas of intermediate thickness (0.76–1.69 mm)²⁵³⁶ and stage II melanomas.²⁵³⁷ There is evidence that the site distribution of melanomas is slightly different today from that seen in the 1970s. Whether this has prognostic significance remains to be determined.²⁵³⁸ As a rule, tumors in less visible body areas are significantly thicker at the time of diagnosis than those occurring in more visible areas.²⁵³⁹ Melanomas in hair-bearing regions of the scalp have a considerably worse prognosis than tumors in other areas of the scalp. The overall survival for patients with melanoma of the ear and nose depended only on the tumor thickness and the Clark level.²⁵⁴⁰ The overall 10-year survival rates for melanoma of the head and neck are similar to those for melanoma at other sites (non-head and non-neck).²⁵⁴¹ In primary uveal melanoma, posterior location (ciliary body and choroid) predicts a worse outcome.²⁵⁴²

There are conflicting results regarding the influence of *pregnancy* on survival rates.^{2543,2544} A melanoma arising during pregnancy may or may not lead to a worse prognosis than in control groups. One study found that melanomas arising during pregnancy are thicker, on average, than in a control group, but this may be balanced in part by a possible pregnancy-associated prognostic advantage.²⁵⁴⁵ More recent studies have concluded that pregnancy has no adverse effect on melanomas diagnosed during pregnancy.²⁵⁴⁶ However, pregnancy seems to have no effect on patients who have had a melanoma diagnosed and treated prior to the pregnancy.^{2544,2547} In a large study from California of 412 women with melanoma diagnosed during or within 1 year after pregnancy, there was no evidence of advanced stages, thicker tumors, increased metastases to lymph nodes, or a worsened survival rate.²⁵⁴⁸ Maternal and neonatal outcomes were equivalent to those of pregnant women without melanoma.²⁵⁴⁸ Similar findings have been reported from The Netherlands.²⁵⁴⁹ Isolated cases continue to be reported of patients who have suffered adverse consequences of a melanoma during pregnancy or with recent childbirth.^{2550–2552} There appear to be no adverse effects from the use of exogenous hormones by women who have previously been diagnosed with melanoma.³⁸¹

The presence of *vittigo*, usually commencing after the diagnosis of melanoma, appears to be prognostically favorable in patients with secondary melanoma.^{2553–2555} Anti-melanoma autoantibodies have been detected in the sera of these patients.²⁵⁵⁶ The development of autoantibodies in other clinical settings is a favorable prognostic parameter.²⁵⁵⁷

Immunosuppression is a risk factor for melanoma and has a negative impact on prognosis.^{2558,2559} Immunosuppressed organ transplant recipients with thick melanomas have a significantly poorer survival compared to unselected melanoma patients controlled for tumor thickness.²⁵⁶⁰ The natural course of malignant melanoma in HIV⁺ patients is more aggressive compared with that in matched HIV[−] melanoma patients.²⁵⁶¹ Withdrawal of immunosuppression therapy has been shown to cause melanoma regression in isolated reports.²⁵⁶²

Local recurrence of melanoma occurs as a first event, prior to lymphatic disease, in a subset of patients. The prognosis of this group is only slightly better than for the group of patients initially presenting with lymph node metastasis.²⁵⁶³

Chromosomal aberrations

Recent studies have identified several potential prognostic markers based on chromosome copy number changes using FISH or comparative genomic hybridization on primary melanoma samples. In a study

of 97 primary melanomas with at least 5 years of follow-up data, Gerami *et al.* evaluated eight FISH probes directed to chromosomes that are commonly gained or lost in melanoma to assess the prognostic power of these chromosomal aberrations. Gains in 11q13 (*CCND1*) or 8q24 (*MYC*) were linked to poor prognosis and were second only to ulceration in their ability to predict metastasis using multivariate logistic regression analysis.²⁴¹⁰ Amplification of topoisomerase I is another potential marker for poor prognosis, warranting further study.²⁴⁰⁹ In primary uveal melanoma, monosomy 3 (and loss of heterozygosity of *BAP1* on chromosome 3) is highly predictive of metastases.^{2542,2564,2565} Gains in 8q also predict a worse outcome in uveal melanoma patients.^{2542,2564,2565} Chromothripsis (a single catastrophic event in the tumor with massive genomic rearrangements) predicts a poor outcome for melanoma patients.²⁵⁶⁶

Immunohistochemical and molecular biomarkers

Numerous immunohistochemical and molecular biomarkers have been found to be associated with tumor biology and/or patient outcome, but none yet have improved upon the prognostic model that includes local/distant metastases, tumor thickness, ulceration, and mitotic rate.^{2567–2571} Many of these markers have previously been discussed (see p. 889) and also are included as components in tumor progression models (see p. 875). Select examples are included.

One of the most extensively studied areas is cell cycling and proliferation. Mitoses and surrogates have been shown to be helpful in distinguishing melanoma from nevi.²⁵⁷² Although mitotic count has a clear impact on melanoma patient prognosis,^{2418,2419,2478,2479} the data are less firm using immunohistochemical markers of proliferation. Several studies have shown that elevated Ki-67 is an adverse prognostic parameter.^{2573–2577} The mitotic marker PHH3 has shown prognostic importance similar to mitotic count in recent studies and may offer a practical advantage over more subjective mitosis counting.¹⁸⁹⁰

Other immunohistochemical markers that have been associated with tumor progression and/or adverse patient outcomes include the following: decreased MiTF,²⁵⁷⁸ increased IGFBP2 (insulin-like growth factor-binding protein 2),²⁵⁷⁹ increased metallothionein, increased cytoplasmic Wnt5a,²⁵⁸⁰ decreased E-cadherin,^{2581–2583} decreased BRMS1 (breast cancer metastasis suppressor 1),²⁵⁸⁴ decreased SNF5,²⁵⁸⁵ increased EZH2 (enhancer of zeste homolog 2),²⁵⁸⁶ increased MCM4 and MCM6 (minichromosome maintenance 4 and 6),²⁵⁸⁷ increased topoisomerase I/II,²⁵⁸⁸ increased receptor tyrosine kinase,²⁵⁸⁹ increased pleiotrophin,²⁵⁹⁰ activated Akt,²⁵⁹¹ increased laminin-containing periendothelial matrix,²⁵⁹² increased matrix metalloproteinases,^{2593–2596} increased phosphotyrosine,²⁵⁹⁷ increased osteonectin and osteopontin,^{2598,2599} increased Fas,²⁶⁰⁰ increased Skp2, increased vascular endothelial growth factor, increased CXCR2 and CXCL8,²⁶⁰¹ increased CXCR3,²⁵⁸² increased Cdc42 and CXCR4,²⁵⁸² increased RGS1 (regulator of G protein signaling),²⁶⁰² increased dysadherin,²⁶⁰³ increased nestin,²⁶⁰⁴ increased fatty acid synthase,²⁶⁰⁵ increased XIAP (X-linked inhibitor of apoptosis protein),²⁶⁰⁶ increased PLK1 (polo-like kinase 1),²⁶⁰⁷ decreased h-caldesmon and calponin h1 in blood vessels,²⁶⁰⁸ decreased claudin-1,²³⁶² decreased β -catenin,²⁵⁸³ decreased cytoplasmic P-cadherin,²⁶⁰⁹ decreased membranous DCXR (dicarbonyl/L-xylulose reductase),²⁶¹⁰ and decreased p21, p27, p53, Rb, Bax, and Bak,²⁶¹¹ among many others.

Many of the previously mentioned immunohistochemical biomarkers have also surfaced as potential prognostic markers using molecular techniques, such as RT-PCR, *in situ* hybridization, gene expression (RNA) microarrays, and microRNA expression arrays. Recently, comprehensive gene expression (transcriptome) profiling of primary and metastatic melanomas has revealed candidate prognostic biomarkers.^{1573,2612,2613} In general, increased expression of genes involved in cell cycle progression, DNA replication, DNA repair, and survival (anti-apoptosis) are observed with tumor progression. Decreased expression of tumor suppressor genes, genes involved in melanocyte

differentiation, and cell adhesion are observed with tumor progression. Select molecular biomarkers associated with a poor prognosis in melanoma patients include the following (increased/decreased refers to mRNA/miRNA levels or *in situ* hybridization signals): increased *SPP1* (osteopontin);²⁶¹⁴ increased *BIRC5* (survivin);¹⁵⁷³ increased *HMG2* (high mobility group AT-hook 2);²⁶¹⁵ increased *CDCA2* (cell division cycle associated 2);¹⁵⁷³ increased *TWIST1* (twist family 1);²⁶¹⁶ increased *TYRP1* (tyrosinase-related protein 1);²⁶¹⁷ increased *NCAPH*, *NCAPG*, and *NCAPG2*;¹⁵⁷³ increased microRNA-15b;²⁶¹⁸ increased *CTSB* (cathepsin B) and *CTSL* (cathepsin L);²⁶¹⁹ increased *HDC* (histidine decarboxylase);²⁶²⁰ decreased *MAGEA3* (melanoma antigen family A, 3);²⁶²¹ decreased *CDKN2A* (cyclin-dependent kinase inhibitor 2A);²⁶²² decreased melanostatin (melanocyte-inhibiting factor);^{2623,2624} and decreased *CDH1* (E-cadherin), *CDH3* (P-cadherin), *PAX3* (paired box 3), *TYR* (tyrosinase), *MC1R* (melanocortin 1 receptor), and *OCA2* (oculocutaneous albinism II).¹⁵⁷³ More recently, panels of genes have been compiled and, using gene expression analysis, the data effectively stratify melanoma patients into low-risk (class 1) and high-risk (class 2) groups.²⁶²⁵ Gene expression profile analysis for prognostic stratification is available commercially for uveal and cutaneous melanoma patients.^{2626,2627}

Identification of low-level circulating tumor cells is now possible using highly sensitive techniques. Identification of these circulating cells has potential for prognostic value at the time of diagnosis as well as predicting relapse during treatment for melanoma patients.²⁶²⁸ The practical utility of this technique is currently under investigation.

Features with no prognostic implications

The following factors have not been shown to have independent prognostic significance, according to various studies: regression,^{1969,1971,2629–2631} surface area (or diameter) and shape of the lesion,^{2632–2634} cell type,²⁶³⁵ pigmentation,²⁶³⁶ incisional biopsy prior to excision,^{2637,2638} and time between the diagnostic excision biopsy and wide local excision of the melanoma (these data are most firm if the interval is <92 days, according to one study).²⁶³⁹

Management of melanoma

Melanoma is primarily a surgically treated disease, and surgery remains virtually the only necessary treatment modality for thin melanomas. Exceptions to this have been briefly mentioned in the sections on the various types of melanoma. Treatment for the advanced melanoma patient recently has become more complex. In addition to palliative surgery, by the late twentieth century, patients with metastatic melanoma could be offered cytotoxic chemotherapeutic agents, specifically dacarbazine (DTIC) and temozolomide, IFN- α , high-dose IL-2, and radiation.^{2640,2641} Although these regimens initially shrink the total tumor burden, there is minimal impact on overall survival. The median survival for stage IV disease is approximately 1 year, and only 10% of patients are long-term survivors.^{2418,2419} Moreover, these treatment regimens are hampered by a high toxicity profile, severely diminishing quality of life during the final year. More recently, therapies that modulate the immune system and others that target specific molecular defects within the tumor cells have brought hope for improving survival for the individual advanced melanoma patient. An extensive discussion of treatments for melanoma is beyond the scope of this book. The following topics are briefly discussed:

- Resection margins
- Handling re-excision specimens
- Lymphatic invasion and lymph node evaluation
- Targeted therapy and immunomodulation.

Resection margins

The surgical treatment of primary melanoma is subject to different guidelines in different countries.^{2642–2644} Controlled studies suggest that

arbitrary wide margins of excision are not justified.^{2446,2645-2649} Local recurrence rates for thick melanomas are increased when the surgical margin is less than 3 cm, although the overall survival rates do not appear to be affected.²⁶⁵⁰⁻²⁶⁵² The available studies provide the rationale behind current recommendations for the excision margins for melanomas of various Breslow depths:^{2653,2654}

- Melanoma *in situ*: 0.5- to 1-cm margins
- ≤1 mm: 1-cm margins
- 1.01–2 mm: 1- to 2-cm margins (1 cm in anatomically restricted sites)
- >2 mm: 2-cm margins.

Despite these various recommendations, the topic of surgical margins remains controversial. Piepkorn and Barnhill stated that ‘the choice of a resection margin materially more than 1 cm has no basis in scientifically observable fact’.^{2655,2656} Several studies have shown that many dermatologists do not adhere to excision guidelines.^{1687,2644} General surgeons, Mohs micrographic surgeons, and dermatologists likely vary in their approaches. Most surgeons take additional tissue as recommended previously, whereas some subtract the clearance of the initial diagnostic specimen from the recommendations.²⁶⁵⁷ The recommended margins often are reduced for cosmetic reasons when treating facial lesions.²⁶⁵⁸ Several authors have argued that 0.5 mm is too narrow for melanoma *in situ* (specifically lentigo maligna).²⁶⁵⁹⁻²⁶⁶¹ Zitelli’s group suggested 0.9 mm as a better margin for melanoma *in situ*, clearing 98.9% of cases (compared to 86% with a 6-mm margin).²⁶⁵⁹

Re-excision specimens

This is the appropriate place to consider the laboratory’s approach to the handling of re-excision specimens. Studies have shown that in the absence of a macroscopic abnormality, the detection of a residual lesion in the re-excision specimen of a completely excised lesion is unusual.²⁶⁶² Accordingly, small block numbers have been recommended in these circumstances, with sampling restricted to the center of the previous excision biopsy scar.^{2662,2663}

Lymphatic invasion and sentinel lymph node biopsy

Despite the significant number of melanoma patients with lymph node metastases, lymphatic invasion has been noted infrequently in primary melanomas. The detection of lymphatic invasion has been enhanced by the use of the immunostain D2-40, which detects podoplanin in lymphatic endothelium. If its use is augmented by multispectral imaging analysis, lymphatic invasion can be detected in 33% of melanomas, in contrast to the less than 5% detection rate on H&E morphology alone.²⁶⁶⁴ Lymphatic invasion is significantly associated with time to regional nodal metastatic disease and melanoma-specific death.²⁶⁶⁴

Lymphatic mapping and SLN biopsy, a technique first published in 1992,²⁶⁶⁵ have had a significant impact on the management and prognostication of patients with melanoma.²⁶⁶⁶⁻²⁶⁷⁰ The SLN is defined as the first node in the lymphatic basin that drains the lesion in question.²⁴³⁵ It is at the greatest risk for the development of a metastasis.²⁶⁷¹ Sometimes the SLN may be outside established standard lymph node basins.²⁶⁷² The status of the SLN is a powerful predictor of recurrence rates and survival for most solid tumors, including melanoma.^{2671,2673,2674} Aggressive features in primary tumors, such as tumor thickness, mitotic rate, ulceration, and angiolymphatic invasion, predict SLN positivity.²⁶⁷⁵⁻²⁶⁷⁸

More recently, the role of SLN biopsy, including its predictive value and morbidity, was studied in an international effort designated the Multicenter Selective Lymphadenectomy Trial-I (MSLT-I).²⁶⁷⁴ Using these results and other studies, the American Society of Clinical Oncology (ASCO) and the Society of Surgical Oncology (SSO) joint clinical practice guidelines were published in 2012 and recommend SLN for all patients with intermediate-thickness melanoma (1.01–4.0 mm), of any anatomic site.²⁶⁷⁹ These authors state that there is

insufficient evidence to perform SLN biopsy in patients with thinner melanomas, but the procedure can be considered in patients harboring tumors with more aggressive features (0.75–0.99 mm tumor thickness, ≥1 mitosis/mm², and ulceration).²⁶⁷⁹ Performing SLN biopsy may also be considered in patients with tumors greater than 4.0 mm, although this would be only for staging purposes.²⁶⁷⁹⁻²⁶⁸¹ If histological examination reveals melanoma metastasis in the SLN, completion lymphadenectomy should be performed and adjuvant therapy considered.^{2679,2682} Approximately 10–25% of patients with a positive SLN will have evidence of tumor in the completion lymphadenectomy specimen.²⁶⁸³⁻²⁶⁸⁵

Although the calls for using SLN biopsy as a standard of care in appropriately selected patients have increased,^{2686,2687} there remain controversies surrounding its use.²⁶⁸⁸⁻²⁶⁹¹ Medalie and Ackerman stated that it has no benefit for the patients whose melanoma has metastasized to a lymph node.²⁶⁹² A review article by Ariyan and Coit from the Memorial Sloan-Kettering Cancer Center in New York stated that the procedure was primarily a staging tool.²⁶⁹³ Some data suggest that patients (the patients in this study had truncal primary tumors >1.5 mm) with a microscopically positive SLN biopsy followed by completion lymphadenectomy have a slightly better survival than patients who develop clinically positive lymph nodes following wide excision alone.²⁶⁹⁴ Another study suggested a slightly better survival in the group of patients with 1- to 2-mm non-ulcerated primaries who received a completion lymphadenectomy.²⁶⁹⁵ Large, appropriately powered studies to address the question of a survival benefit from SLN biopsy/completion lymphadenectomy are needed. Use of SLN biopsy for recurrent low-stage tumors, transected tumors, histologically ambiguous (nondiagnostic) tumors, pure desmoplastic tumors, and in patients who have already received a large wide excision is controversial.^{609,2696,2697}

The handling of the SLN by the laboratory should be done in accordance with protocol. Protocols have been published,^{2172,2682,2698-2702} although a uniformly accepted standard does not exist. Many laboratories will bisect all material submitted as ‘sentinel node’ along the long axis, regardless of the number of lymph nodes, and generate one or more H&E slides, sometimes with interval unstained slides to be used for immunohistochemistry, if needed. In negative or suspicious cases, immunohistochemistry for some combination of MART-1, SOX-10, and gp100 (HMB-45), or a melanocyte-specific cocktail, is performed. Immunohistochemistry increases sensitivity.^{2682,2703,2704} Distinction between micrometastases and nodal nevi can be challenging. Features favoring a metastasis include parenchymal involvement (as opposed to capsular), cytologic atypia, increased Ki-67 expression, and expression of gp100 (HMB-45).^{2705,2706} There is a whole body of literature devoted to PCR and RT-PCR evaluation of sentinel lymph nodes to determine prognosis.²⁴³⁷⁻²⁴⁴¹ In general, as expected, using these molecular approaches has increased the sensitivity for detecting a positive sentinel lymph node, and the more markers used, the higher the sensitivity. One of the main barriers to widespread use, however, is the lack of a good melanoma-specific marker because targets to distinguish melanoma from a nevus are not available. Moreover, nodal nevi are more common in SLN than in other lymph nodes,²⁷⁰⁷ and nodal nevi are more common among melanoma patients compared to non-melanoma patients.⁹⁴¹ New potential melanoma-specific markers are continually being discovered and evaluated, raising the possibility for future applications.²⁷⁰⁸ Fine needle biopsy with ultrasound guidance may be useful for the evaluation of lymph node status in some settings.²⁷⁰⁹ Nodal metastases potentially can be detected by FISH (and distinguished from a nodal nevus) if the primary tumor has a signature chromosomal aberration.²⁴⁰⁷ Detecting *BRAF* V600E in the lymph node does not appear to have value because this mutation is also present in nodal nevi.²⁷¹⁰

Frozen section assessment of the SLN is not warranted, in view of the low sensitivity of this procedure²⁷¹¹ and the loss of tissue that

results from this process.²⁷¹² Frozen section with rapid immunohistochemistry has been advocated as a means of obviating the need for two surgical procedures, should positive nodes be found,²⁷¹³ although this practice is not widely embraced.

Targeted therapy for advanced disease

In the wake of the landmark vemurafenib study (see later), the number of clinical trials for advanced melanoma has grown exponentially.²⁷¹⁴ Drug development has been focused on targeting aberrantly activated oncoproteins because this is much more achievable than reconstituting the function of absent or dysfunctional tumor suppressor proteins.²⁷¹⁴ Targeted therapy has revolutionized the cancer treatment paradigm, shifting the focus away from treating tumors based on anatomic site or cell of origin and toward treating tumors based on specific molecular events that drive oncogenesis. Select examples that recently have shown the most promise are discussed.

B-Raf mutations are common in cancer, specifically melanoma, but early pharmacologic attempts to block activated B-Raf achieved only minimal success.²⁷¹⁵ Recently, a series of preclinical studies and clinical trials culminated in the FDA approval of *vemurafenib*, a selective B-Raf^{V600E} inhibitor, for treatment of advanced-stage melanoma.^{1201,2411} Vemurafenib is an ATP-competitive Raf inhibitor specific for the B-Raf^{V600E} mutant protein. In the phase III randomized clinical trial comparing vemurafenib (960 mg twice daily) with dacarbazine (1000 mg/m² i.v. q3weeks), 675 patients with untreated stage IIIC or stage IV melanoma harboring the *BRAF* V600E mutation had better overall and progression-free survival rates when treated with the B-Raf inhibitor. At 6 months, the overall survival was 84% in the treatment arm compared to 64% in the dacarbazine arm. The median progression-free survival was 5.3 months in the vemurafenib group compared to 1.6 months in the dacarbazine group. The main reported adverse events include arthralgias, fatigue, rash, alopecia, and cutaneous tumors.¹²⁰¹ The cutaneous tumors range from benign verrucous keratoses to keratoacanthomas to invasive squamous cell carcinomas.²⁷¹⁶ The cutaneous tumors appear driven by paradoxical activation of the MAP kinase pathway, directly or indirectly through activated N-Ras or H-Ras.^{2414,2717–2719} These side effects can be abrogated by treating patients with inhibitors to downstream MAP kinase molecules, such as MEK (see later). Overall, the side effects of this therapy have been transient and manageable.¹²⁰¹

Since vemurafenib, other B-Raf inhibitors have emerged. *Dabrafenib* is also a selective B-Raf^{V600E} inhibitor with a similar impact on progression-free survival as vemurafenib.²⁷²⁰ Dabrafenib has been reported to have fewer cutaneous side effects than vemurafenib, a good safety profile for patients with brain metastases,²⁷²¹ and apparent activity against alternate B-Raf mutant proteins such as B-Raf^{V600K} and B-Raf^{V600R}.²⁷²² RAF-265 and LGX818 are other selective inhibitors of B-Raf currently being investigated.

As the vemurafenib and dabrafenib studies show, treatment with a single agent B-Raf^{V600E} mutant inhibitor, while transiently effective, is no definitive cure.^{1201,2720} After an initial dramatic tumor response to inhibitor therapy, in many cases, the melanoma recurs, with a median progression-free survival of 5.3 months. In addition, almost half of the patients with *BRAF* V600E-mutated melanoma had no objective responses, suggesting that pre-therapy resistance, or primary resistance, mechanisms were already in place.

MEK and/or **ERK** inhibition may become an effective strategy to shut down activated melanoma cells because these molecules lie downstream in the MAP kinase signaling pathway. Almost all melanomas have an activated MAP kinase pathway, culminating in activated MEK and ERK, whether by mutated B-Raf, N-Ras, GNAQ/GNA11, or other molecule. Clinical trials using MEK inhibitor monotherapy had been disappointing until recently.²⁷²³ *Trametinib* is an allosteric MEK1/2 inhibitor recently FDA-approved for the treatment of advanced or surgically unresectable melanoma. Trametinib is a MEK inhibitor but

has been shown to be moderately effective for treating B-Raf^{V600E} or B-Raf^{V600K} mutant melanomas, and it was FDA-approved for this purpose. In the phase I trial for trametinib, Falchook *et al.* reported a 33% response rate in previously untreated patients harboring a *BRAF*-mutated melanoma.²⁷²⁴ The phase II trial for trametinib showed significant clinical activity in patients who had not previously received mutant B-Raf inhibitor therapy (2% complete response, 23% partial response, and 51% stable disease; *n* = 57).²⁷²⁵ Interestingly, patients who had been previously treated with mutant B-Raf inhibitor therapy did not fare as well, suggesting that MEK inhibition monotherapy may not be effective in this resistant or relapsed patient group. *MEK162* is another MEK inhibitor. MEK162 has activity against B-Raf mutated melanomas and is one of the first pharmacologic agents to demonstrate clinical efficacy, albeit modest, against *NRAS*-mutated tumors.²⁷²⁶ *GDC-0973*, *selumetinib*, and *pimasertib* are other examples of MEK inhibitors currently under investigation.^{2727,2728} *SCH772984* and *AEZS-131* are examples of ERK inhibitors under development, with little data currently available.²⁷²⁹ Even with the promising results of trametinib monotherapy, the real value in MEK and ERK inhibition may be realized in other settings: as rescue therapy for B-Raf-inhibitor-resistant tumors, as a treatment for *NRAS*-mutated melanomas, and as combination therapy with other agents.

Kit inhibitors, such as *imatinib mesylate*, have been around for more than a decade, mainly due to their efficacy against gastrointestinal stromal tumors (GISTs) and chronic myelogenous leukemia (CML).^{2730,2731} Initial trials for melanoma showed minimal or no benefit.^{2732,2733} More recent phase II open-label clinical trials explored the efficacy of Kit inhibitor therapy on patients with advanced melanoma with known aberrations to *KIT*, not just immunohistochemical expression levels, and obtained more promising results.^{1535,2417,2734,2735} The efficacy of Kit inhibitor therapy appears to be linked to the type of *KIT* aberration.^{1535,2417,2735} In a study by Carvajal *et al.*, all responders had mutations in either exon 11 (L576P) or exon 13 (K642E).¹⁵³⁵ Guo *et al.* reported that only patients with mutations in exons 11 or 13 (and one patient with *KIT* amplification but no mutation) responded to therapy.²⁷³⁵ Hodi *et al.* examined the efficacy of imatinib mesylate in specific subtypes of melanomas with high frequencies of *KIT* aberrancies (acral, mucosal, and chronically sun-damaged skin melanomas).²⁴¹⁷ These investigators also observed better responses with *KIT*-mutated tumors rather than *KIT*-amplified tumors.²⁴¹⁷ Patients with functional *KIT* mutations respond better than patients with *KIT* amplifications or nonfunctional mutations. Kit expression levels, as determined by immunohistochemistry, do not correlate with response to therapy.^{1534,2367} Secondary *KIT* mutations appear to be the main mechanisms of resistance to Kit inhibitor therapy.^{2730,2736} *Nilotinib*, *sunitinib malate*, *dasatinib*, *sorafenib tosylate*, *masatinib mesylate*, and *midostaurin* are newer-generation Kit inhibitors currently in early clinical trials.^{2714,2737}

Pharmacologic inhibition to other molecules activated in melanoma is being investigated. Candidate molecules to target, as monotherapy or in combination regimens, include the following: N-Ras, PI3K, Akt, mTOR and the mTOR complexes mTORC1/2, GNAQ/11, and others.^{2714,2738–2743}

Immunotherapy and immunomodulation

Modification of the immune system has attained recent success as a strategy in the treatment of advanced melanoma. Mechanisms include vaccines, adoptive T cell therapy using autologous tumor-infiltrating lymphocytes, cytokine therapy, and immunomodulatory agents, with many available reviews on the topic.^{2744–2747} A thorough discussion of immunotherapy is beyond the scope of this text, but a few strategies are briefly mentioned here.

High-dose IL-2 (aldesleukin) has been used for treating metastatic melanoma for more than a decade. It can induce partial responses in subsets of patients, but it has little effect on overall survival and is

associated with significant toxicity.²⁶⁴⁰ More recent data indicate that melanomas with *NRAS* mutations respond better to IL-2 than do tumors with wild-type *NRAS*.¹⁵⁰⁸ *Ipilimumab* is a monoclonal antibody that acts as an immunomodulator, and it was recently FDA-approved for the treatment of advanced melanoma.²⁷⁴⁸ *Ipilimumab* binds to CTLA-4 (cytotoxic T lymphocyte antigen 4), reducing the activity of T_{regs}, thus enhancing the overall immune response. In the phase III study comparing ipilimumab with or without the gp100 peptide vaccine compared to the gp100 vaccine alone, patients receiving ipilimumab (either group, $\pm$ gp100) had a median overall survival of 10.0 months compared with 6.4 months in the gp100-only group.²⁷⁴⁹ *Ipilimumab*, as with other immune-activating therapies, can lead to immune-related adverse events involving the skin, gastrointestinal tract, liver, and endocrine system. *Tremelimumab* is also a CTLA-4 blocker with a slightly longer half-life that is currently under investigation.²⁷⁵⁰ *Lambrolizumab* is a recently FDA-approved antibody directed against the programmed cell death 1 (PD-1) pathway.²⁷⁵¹ The PD-1 receptor on activated T cells normally binds to ligands on antigen-presenting cells, shutting down the immune response. *Lambrolizumab* interferes with this process, causing a heightened immune response with antitumor activity. *Nivolumab* is a newer drug with a similar mechanism of action.

Combination therapy and emerging therapeutic strategies

Simultaneous targeting of multiple checkpoints along series or parallel circuits within malignant cells may provide a greater initial tumor response and may minimize resistance.^{2752,2753} Initial data using B-Raf inhibitor/MEK inhibitor combination therapy has been promising, with better clinical activity and fewer cutaneous cancers than B-Raf inhibitor monotherapy.²⁷⁵⁴ Combinations of MAP kinase inhibitors and inhibitors of other pathways (PIK3/Akt/mTOR, p16/CDK4/Rb, etc.) are also being explored.²⁷¹⁴ Strategies behind combination therapies are not limited to the MAP kinase and related signaling pathways. In fact, there is theoretical (and realized) benefit to using therapies with completely different mechanisms of action. Data indicate that chemotherapy and/or B-Raf (and/or MEK) inhibitor therapy may cause melanoma to be more immunogenic, perhaps by exposing melanoma-specific antigens upon melanoma cell death. This would predict a potentially synergistic effect by using a combination approach of a B-Raf inhibitor followed by ipilimumab therapy.^{2714,2755,2756} A rationale also exists for trying various combinations of the above with antiangiogenesis therapy (bevacizumab, an anti-VEGF antibody), antiapoptosis therapy (oblimersen, a bcl-2 antisense molecule), other immunotherapy (lambrolizumab), possibly autophagy or telomerase modulators, and others. Many of these have been discussed in recent reviews.^{2757,2758}

BAP1-INACTIVATED MELANOCYTIC TUMORS

Inactivation of the *BAP1* tumor suppressor gene recently has been described in sporadic cutaneous melanomas and in the *BAP1* hereditary cancer predisposition syndrome, which is associated with uveal melanomas and cutaneous melanomas, among other tumors.^{1457–1460} *BAP1*-inactivated uveal and cutaneous melanomas appear to have a worse prognosis than their wild-type counterparts in both the familial and the sporadic setting.^{1458,1496} In sporadic cutaneous melanomas, loss of *BAP1* expression is observed in all histologic subtypes, with one recent study suggesting a disproportionate overrepresentation of desmoplastic melanoma.¹⁴⁹⁶

Individuals with the *BAP1* hereditary cancer predisposition syndrome can develop unequivocal cutaneous melanomas as well as a spectrum of atypical Spitzoid tumors, some of which may progress to melanoma.^{1457,1461,1495} These lesions most commonly occur on the trunk and are usually not pigmented.

Figure 32.49 Melanocytic *BAP1*-mutated atypical intradermal tumor. Enlarged epithelioid cells with moderate pleomorphism populate the dermis. A mitosis is present near the middle of the image. *BAP1* expression is lost by immunohistochemistry (not shown). (H&E)

Histopathology

The atypical Spitzoid tumors form a dermal nodule or nodules of large atypical cells (Fig. 32.49). The cells are epithelioid with well-defined cytoplasmic borders. In many cases, the cells have moderate pleomorphism and prominent nucleoli. An inflammatory component is commonly observed. Mitoses are often present but are not numerous. These tumors lack other histologic features of Spitz nevi, such as epidermal hyperplasia, a prominent junctional component, Kamino bodies, vertically oriented nests with prominent clefting, and cells with spindled morphology. Further distinguishing these lesions from Spitz nevi are a high frequency of concurrent *BRAF* V600E mutations (which are not present in Spitz nevi) and lack of *HRAS* mutations (which are present in a subset of Spitz nevi).¹⁴⁹⁵ Some authors have proposed the term melanocytic *BAP1*-mutated atypical intradermal tumor (**MBAIT**) for these lesions until their true biology is better characterized.¹⁴⁶⁰ Some lesions will have unequivocal malignant features (pleomorphism, high mitotic rate, ulceration, etc.), possibly, in a subset of cases, representing malignant transformation. Other (sporadic) *BAP1*-inactivated melanomas may be difficult to histologically distinguish from *BAP1* wild-type melanomas.¹⁴⁹⁶ Loss of nuclear staining by *BAP1* immunohistochemistry is an effective surrogate for *BAP1* functional inactivating mutations and deletions.¹⁴⁹⁵

PIGMENTED EPITHELIOID MELANOCYTOMA

The term ‘pigmented epithelioid melanocytoma’ was coined by Zembowicz *et al.* for a ‘low-grade melanocytic tumor with metastatic potential indistinguishable from animal-type melanoma and epithelioid blue nevus’.²⁷⁵⁹ As such, it is a heterogeneous entity, but use of this term acknowledges that heavily pigmented nevomelanocytic tumors occur on which it is impossible to prognosticate. They occur at all ages, but there is a tendency for them to occur in younger persons. The median age of the 40 patients in the series from Zembowicz *et al.* was 27 years.²⁷⁵⁹ Congenital cases have since been reported.^{2760,2761} Regional nodes contained metastases in 11 of the 24 cases sampled, and liver metastases occurred in 1 patient.²⁷⁵⁹ No deaths have occurred, but the follow-up period has been short. More recently, in a follow-up study from North America and Australia, of 26 patients with pigmented

epithelioid melanocytoma, 8 had lymph node involvement but all were alive and disease-free at a median follow-up period of 67 months.²⁷⁶² A case has been reported in the conjunctiva²⁷⁶³ in Japanese patients,²⁷⁶⁴ in a patient with Becker nevus syndrome,²⁷⁶⁵ and in an HIV⁺ person.²⁷⁶⁶

Ackerman was a vocal critic of this entity, even devoting a monograph to it.^{2767,2768} Others have also been critical.^{2769,2770} Antony *et al.* suggested 'pigment synthesizing melanoma' as a preferable term.²⁷⁷¹ Scolyer *et al.* documented their experience with 45 cases and commented on the unusually high incidence of positive sentinel nodes in the series from Zembowicz.^{2759,2772} Scolyer *et al.* grouped such lesions as 'melanocytic tumors of uncertain malignant potential'. Cases of neurocristic cutaneous hamartoma that underwent malignant transformation have also been included as pigmented epithelioid melanocytomas.¹⁰⁰⁶ Regardless of its designation, most authors agree that it should be treated as a melanoma.^{2771,2773} Sentinel lymph node biopsy is carried out in some countries.²⁷⁷⁴

Interestingly, transgenic mice expressing hepatocyte growth factor develop cutaneous melanocytic tumors following neonatal UV exposure that resemble pigmented epithelioid melanocytomas.²⁷⁷⁵ Furthermore, there is a loss of expression of the regulatory subunit type 1 α (R1 α), coded by the *PRKARIA* gene, in most pigmented epithelioid melanocytomas, which also occurs in epithelioid blue nevi in the Carney complex.²⁷⁷⁶

Histopathology

In the original series from Zembowicz *et al.*, it was not possible to distinguish cases of epithelioid blue nevus occurring in the Carney complex from other tumors categorized as pigmented epithelioid melanocytoma.²⁷⁵⁹

The lesions are heavily pigmented dermal melanocytic tumors with infiltrative borders. They may extend into subcutis. A minor junctional component is sometimes present. Ulceration is present in a small number of cases; others may have epidermal hyperplasia.²⁷⁵⁹ The tumor is composed of a mixture of epithelioid and spindled melanocytes with heavy pigmentation (Fig. 32.50). Spindle cells are more common at the periphery. Melanophages usually account for less than 10% of the cells. Mitoses are usually infrequent.

The case reported as intraepidermal animal-type melanoma may have been another entity.²⁷⁷⁷

To date, *BRAF* mutations have not been identified.²⁷⁶⁰ FISH data are limited, with several cases demonstrating no abnormalities and one

case with a gain in chromosome 6.^{2760,2778} Ultrastructural studies have provided unequivocal evidence that this tumor is a neoplasm of melanosome-producing cells.¹⁰⁰⁶

CLEAR CELL SARCOMA

Clear cell sarcoma (melanoma of soft parts) is a rare soft tissue tumor derived from neural crest cells.^{924,2779–2781} It may involve the skin secondarily. Rarely, a dermal nodule of the tumor may be a major component. Such cases may present as painful ulcers.²⁷⁸² It arises mainly in adolescents and young adults, but there is a wide age range. The extremities, particularly the lower, are commonly involved. It behaves as a high-grade sarcoma and its course is marked by frequent local recurrences, with eventual metastasis in many to regional lymph nodes and lungs.²⁷⁸³ The 10-year survival rate was 36% in one series of 75 patients.²⁷⁸⁴

Wide local excision is the treatment of choice. Sentinel lymph node biopsy has been used to guide the extent of surgery.²⁷⁸⁵ The beneficial effects of adjuvant chemotherapy and radiotherapy have not been fully evaluated.^{2780,2784} Various chemotherapy cocktails have been used.²⁷⁸²

Histopathology

The tumor is composed of nests and strands of relatively bland oval or elongated cells separated by thin collagenous septa. Large amounts of pale or granular amphophilic cytoplasm are present (Fig. 32.51).²⁷⁷⁹ Melanin and glycogen can be demonstrated in approximately two-thirds of cases. Stromal mucin is found in the rare myxoid variant.²⁷⁸⁶ Multinucleate tumor cells are often present, but mitoses may be scarce. The cells express S100 protein and/or gp100 (HMB-45). MART-1 (melan-A) is often positive, but CD117 is infrequently expressed or not at all.^{2787,2788} Keratin markers, such as CAM5.2, are expressed in up to one-third of cases, although the incidence of keratin markers was much lower in one study.²⁷⁸⁷

A specific chromosomal translocation involving chromosomes 22 and 12 characterizes 60% of cases. The translocation is t(12;22)(q13;q12); this creates a unique chimeric fusion *EWSR1-ATF1* gene transcript, occurring in approximately 70–80% of cases.^{2789–2791} This transcript may be detected in paraffin-embedded tissues by RT-PCR.²⁷⁹² Other methods, such as FISH, can also be used.²⁷⁹³ A minority of cases (<5%) have a t(2;22) translocation, but this is observed more commonly in tumors of the gastrointestinal tract.²⁷⁹⁴

Figure 32.50 Pigmented epithelioid melanocytoma. This lesion from a 9-year-old male had a positive sentinel lymph node. (H&E)

Figure 32.51 Clear cell sarcoma. This image shows groupings of rounded to slightly fusiform cells with clear to faintly granular cytoplasm, divided by fibrous tissue septa. (H&E)

Figure 32.52 Squamo-melanocytic tumor. (A) This lesion is not connected with the surface. (B) There is an intimate admixture of squamous cells and cytologically malignant melanocytes that stained with HMB-45. (H&E)

MELANOCYTONEUROMA

This term was used in 2007 for a nerve sheath tumor with melanocytic differentiation and intraneural location.²⁷⁹⁵ It consisted of a dermal nodule with an intraneural proliferation of large epithelioid eosinophilic cells with prominent cell borders imparting a ‘plant-like’ appearance.²⁷⁹⁵ The cells expressed S100 protein, HMB-45, melan-A, and MITF.

SQUAMO-MELANOCYTIC TUMOR

Four cases of squamo-melanocytic tumor were described in 1999, although a similar case had been described much earlier.²⁷⁹⁶ The four cases developed on the face of middle-aged and older individuals as a purple-black nodule, ranging in size from 3 to 10 mm. Neither recurrence nor metastasis has developed following complete excision and a mean follow-up period of 3.25 years. However, in a recent case of squamo-melanocytic tumor involving the thumbnail, micrometastasis of the melanoma component was found in an axillary sentinel lymph node.²⁷⁹⁷

Figure 32.53 Baso-melanocytic tumor. (A) This appears to be the basaloid equivalent of squamo-melanocytic tumor. (H&E) (B) The intimate admixture of basaloid cells and melanocytes (or biphenotypic differentiation) can be seen on this S100 preparation. (Immunohistochemistry for S100 protein)

This tumor appears to represent a biphasic neoplasm with features of malignancy and uncertain biological behavior.²⁷⁹⁶ The author has seen five such cases, but their fate is unknown.

Histopathology

The lesion usually presents as a discrete dermal nodule surrounded by a fibroblastic stroma. In most instances, there is no connection with the overlying epidermis and no epidermal component. However, in one of the reported cases and in two personally studied cases, there was connection to an overlying lentigo maligna component.

The tumor is composed of two cell types that are diffusely admixed or clustered in small groups within the nodule.²⁷⁹⁶ The squamoid component comprises atypical epithelial cells with focal formation of squamous pearls. The other component consists of small, atypical epithelioid cells with nuclear atypia and cytoplasmic melanin (Fig. 32.52). A recent example of squamo-melanocytic tumor featured focal matrical differentiation and perineural invasion by the squamous cell component.²⁷⁹⁸ The pigment-containing cells express S100 protein, with fewer cells expressing HMB-45, whereas the squamoid cells stain for cytokeratin.²⁷⁹⁶

The intimate admixture of the two components distinguishes this lesion from the more common collision tumor that may involve malignant melanoma as one component and basal cell carcinoma^{2799–2803} or squamous cell carcinoma as the other.^{2804,2805} Biphenotypic tumors with dedifferentiated cells, but two components on immunohistochemistry, have also been reported (Fig. 32.53).²⁸⁰⁶ A **malignant baso-melanocytic tumor** manifesting as metastatic melanoma has also been reported.²⁸⁰⁷ A squamous cell carcinoma *in situ* of the skin with melanocyte colonization is another variation on this biphasic theme.²⁸⁰⁸ So too is the tumor reported as a follicular baso-squamous melanocytic tumor.²⁸⁰⁹

The two tumors reported by Rodriguez *et al.* in 2005 as ‘combined high-grade basal cell carcinoma and malignant melanoma of the skin (‘malignant basomelanocytic tumor’)’ were regarded as tumors with bidirectional keratinocytic and melanocytic differentiation.²⁸¹⁰

Fibrofolliculoma/trichodiscoma	920	Poroma group	938	Malignant cylindroma	956
Birt–Hogg–Dubé syndrome	920	Apocrine poroma	939	Malignant spiradenoma (spiradenocarcinoma)	956
Neurofollicular hamartoma	921	Eccrine poroma	939		
Malignant pilar neoplasms	921				
Trichilemmal carcinoma	921				

Adnexal carcinomas with distinctive features	956	Microcystic adnexal carcinoma	959	Polymorphous sweat gland carcinoma	964
Mucinous (eccrine) carcinoma	956	Other sweat gland carcinomas	960	Signet-ring cell carcinoma of the eyelid	964
Endocrine mucin-producing sweat gland carcinoma	957	Adenocarcinoma of Moll's glands	960	Small cell sweat gland carcinoma of childhood	964
Adenoid cystic carcinoma	957	Adnexal clear cell carcinoma with comedonecrosis	960	Squamoid eccrine ductal carcinoma	964
Digital papillary adenocarcinoma	958	Apocrine adenocarcinoma	960	Syringoid eccrine carcinoma	965
		Extramammary Paget's disease	961		

INTRODUCTION

The cutaneous appendages give rise to a bewildering number of neoplasms – more than 80 at a recent count. Various classifications have been proposed in the past. The editor initially learned the adnexal tumors by studying the table created by Walter Lever, which at the time was regarded by some as the ‘periodic table of adnexal tumors’. Regrettably, this and other similar classifications have required modification from time to time in light of the most recent ultrastructural and histochemical findings and the reporting of new morphological entities. Ackerman and colleagues systematically reclassified many of the traditional ‘eccrine’ tumors into apocrine categories, based largely on their morphology rather than their histochemical characteristics. The classification used in the previous edition was based, in part, on Ackerman’s writings. The categorization presented here is similar to that used in previous publications and grouped according to hair follicle tumors, sebaceous tumors, and apocrine and eccrine tumors. The latter tumors, whether of apocrine or eccrine origin, are combined into one section, although the possible line of differentiation is considered for many of the individual entities. The goal is to create a convenient, morphologically based system for grouping these lesions from a purely practical perspective, which the editor has found to be helpful; it is by no means the ‘only’ way of classifying these tumors. A review of skin adnexal tumors, in two parts, was published in 2007.^{1,2}

To summarize, the appendageal tumors are considered under the traditional headings:

- Hair follicle tumors
- Sebaceous tumors
- Apocrine and eccrine tumors
- Complex adnexal tumors.

A case could be made on embryological grounds to have only two categories: folliculosebaceous–apocrine and eccrine.³ Increasingly more tumors are being recognized in the first of these two categories with divergent differentiation, although monophasic differentiation is the usual characteristic.

Occasional tumors defy classification, such as the extraparotid Warthin’s tumor and the **ocular adnexal oncocytoma**.^{4–6} The oncocytoma is a benign neoplasm composed of polygonal cells with abundant finely granular eosinophilic cytoplasm. The cells are arranged as sheets with some tubular and cystic spaces.⁷ The cells express pancytokeratin but not S100 or smooth muscle markers.^{7,8} Cytoplasmic immunoreactivity for androgen receptors has been reported.⁸ None of the lesions arising in the caruncle has behaved aggressively, in contrast to occasional tumors in other oculocutaneous sites.⁸ The cell of origin is not known.

Organ transplant recipients have a high frequency and diversity of appendageal tumors.⁹ Their tumors are more likely to be malignant and of sebaceous origin.⁹

HAIR FOLLICLE TUMORS

There is as yet no universally acceptable classification of hair follicle tumors. Headington, in his comprehensive review in 1976, proposed a detailed histogenetic classification,¹⁰ whereas Mehregan in 1985 used a much simpler classification¹¹ with three subgroups: hyperplasias (nevi), adenomas, and epitheliomas. Rosen published a classification in which the benign tumors are divided into seven categories, depending on which part or parts of the hair follicle the lesion differentiates toward or most closely resembles.¹²

In their book on follicular neoplasms, Ackerman, Reddy, and Soyer published, with a critique, the classifications used in eight textbooks of dermatopathology.¹³ No two classifications are the same, although there is some unanimity with regard to the entities that should be regarded as follicular tumors. The classification of Ackerman and colleagues differs in categorization and nomenclature from the one used here.¹³ For example, they classified trichoepitheliomas as trichoblastomas while conceding that what is known as desmoplastic trichoepithelioma is clinically distinctive. Trichilemmomas and inverted follicular keratoses were considered warts, and basal cell carcinomas were renamed trichoblastic carcinoma. It is not proposed to modify substantially the classification previously used for follicular tumors.

The distinction between malignant and benign follicular tumors is usually quite easy on histological examination. In difficult cases, DNA image cytometry may be helpful.¹⁴

NEVOID FOLLICULAR LESIONS

HAIR FOLLICLE NEVUS

These hamartomas are exceedingly rare lesions of the head and neck, presenting as a small nodule or area of hypertrichosis.^{11,15–17} A linear variant has been reported.¹⁸ Such cases may follow Blaschko’s lines.¹⁹ They are composed of closely arranged mature vellus follicles.²⁰ Headington suggested the term ‘congenital vellus hamartoma’ for these lesions.¹⁰ They must be distinguished from accessory tragi, in which many vellus follicles can also be seen.²¹ The hair follicle nevus has been confused with the trichofolliculoma, but they are histologically distinct.²²

Also included in this group is the entity known as ‘faun-tail’, a patch of hairs over the lower sacral area.¹¹ It is relevant to mention here the rare occurrence of hair follicles on the palms and soles.²³ Becker’s

nevus (see p. 337) is sometimes included in the general category of hair follicle hamartomas.¹⁰ A newly described condition with onset in early childhood, consisting of linear lesions of the face, trunk, and arm, has microscopic features of follicular plugging and intrafollicular mucin deposition; it has been termed **nevoid follicular mucinosis**.²⁴

A variant of the linear porokeratotic eccrine ostial and dermal duct nevus (discussed under Eccrine Nevi and Hamartomas), called **porokeratotic eccrine and hair follicle nevus**, features cornoid lamellae within both acrosyringia and follicular infundibula.^{25,26} A nodular lesion first presenting in a 3-month-old child showed admixtures of sweat glands and hair follicles associated with thickened collagen bundles; the authors termed this lesion a **hybrid eccrine gland and hair follicle hamartoma**.²⁷

The term **congenital panfollicular nevus** has been proposed by Finn and Argenyi for a rare lesion of abortive hair follicles arranged in multiple dermal nodules.²⁸ There was some resemblance to folliculosebaceous cystic hamartoma.²⁸ The nodules were surrounded by fibrous sheaths.²⁹

FOLLICULAR HAMARTOMA SYNDROMES

Several extremely rare syndromes are characterized by the development of localized, zosteriform or linear tumors with overlapping histological features. Cases have been both familial and sporadic, and the associated clinical features have been varied. Ackerman has challenged the validity of these syndromes, believing them to be different expressions of infundibulocystic basal cell carcinomas occurring in variants of the nevoid basal cell carcinoma syndrome, although this has been disputed.³⁰ The lesions exhibit fewer mitoses and apoptotic cells than do basal cell carcinomas.³¹ Their Ki-67 labeling is lower than that of basal cell carcinomas.³¹ Some of the cases mentioned here have only a vague resemblance to infundibulocystic basal cell carcinomas. It is acknowledged that they may not all be discrete entities.

Generalized hair follicle hamartoma

Generalized hair follicle hamartoma has been applied to patients with papules and plaques on the face, progressive alopecia, and myasthenia gravis.^{32,33} Cystic fibrosis is a further association of this follicular hamartoma.³⁴ Involved skin shows a spectrum of changes, with some lesions resembling trichoepithelioma and others 'basaloid follicular hamartoma', whereas uninvolved skin may show small islands of basaloid cells.³³ A case with diffuse sclerosis of the face has been reported.³⁵

Basaloid follicular hamartoma

The term 'basaloid follicular hamartoma' was coined by Mehregan and Baker for three patients with localized or systematized lesions in which individual hair follicles were replaced or were associated with solid strands and branching cords of undifferentiated basaloid cells with some intervening fibrous stroma.³⁶ Although they regarded the condition as a localized variant of generalized hair follicle hamartoma, in their cases there was less resemblance to trichoepithelioma and more to a premalignant fibroepithelial tumor of Pinkus.³⁶ A linear variant has also been reported.^{37,38}

Similar cases, both solitary and multiple familial cases, have been reported by Brownstein and others.^{39,40} The lesions remain stable for many years.³¹ They are 1- to 2-mm smooth facial papules composed of anastomosing strands of basaloid and squamoid cells in a loose stroma. Horn cysts and pigmentation are common (Fig. 33.1). It seems that there are four distinctive clinical forms: a solitary papule, a localized plaque of alopecia, a localized linear and unilateral papule or plaque, and generalized papules often with associated alopecia and myasthenia gravis.⁴¹⁻⁴⁴ Increased sonic hedgehog signaling pathways with increased Gli-1 transcription is present in some cases. This may

Figure 33.1 Basaloid follicular hamartoma. There are anastomosing cords of undifferentiated basaloid cells with multiple epidermal connections and a loose surrounding stroma. A horn cyst can be observed on the right side of the lesion. (H&E)

explain the response of one patient to retinoid therapy because retinoids decrease Gli-1 transcriptional activity.⁴²

The family reported by Wheeler and colleagues as having dominantly inherited *generalized basaloid follicular hamartoma syndrome* had clinical and histological differences from Brownstein's cases.⁴⁵ The lesions were composed of nests of bland basaloid cells surrounded by scant fibrous stroma. They were usually associated with hair follicles. There were infundibular cysts and comedone-like lesions, but they had no resemblance to the infundibulocystic basal cell carcinoma.⁴⁵ It has since been suggested⁴⁶ that this family may have a form of Bazex-Dupré-Christol syndrome (Bazex syndrome; OMIM 301845). Notwithstanding this view, Smoller and colleagues have accepted generalized basaloid follicular hamartoma syndrome as an autosomal-dominantly inherited disorder that presents with disseminated milia, palmoplantar pitting, hypotrichosis, and basaloid follicular hamartomas.⁴⁴ Their studies of this syndrome using bcl-2, CD34, and CD10 found similarities in differentiation with trichoepithelioma.⁴⁴ A segmentally arranged basaloid follicular hamartoma with osseous, cerebral, and dental abnormalities has been described by Happle and Tinschert.⁴⁷ A recently reported variant of the syndrome presented as unilateral linear skin lesions associated with ipsilateral hemimegalophaly and microphthalmia.⁴⁸

Linear unilateral basal cell nevus with comedones

Linear unilateral basal cell nevus with comedones refers to linear or zosteriform lesions, some with comedone plugs, that are present at birth or soon after.⁴⁹ Although there is some clinical resemblance to nevus comedonicus (see p. 786), the histology resembles a basal cell carcinoma. Some cases have had a lattice-like growth of basaloid cells attached to the undersurface of the epidermis and vague follicular differentiation. These features were also present in the case reported as **localized follicular hamartoma**.⁵⁰

BENIGN NONGERMINATIVE FOLLICULAR NEOPLASMS

DILATED PORE OF WINER

The dilated pore of Winer⁵¹ is a relatively common adnexal lesion that occurs predominantly on the head and neck, but it also occurs on the

Figure 33.2 Dilated pore of Winer. Acanthotic projections extend from the base of a dilated follicular pore. (H&E)

upper trunk of elderly individuals.⁵² Clinically and histologically, it is a comedo-like structure. Dilated pores may be acquired as a sequel of inflammatory cystic acne or of actinic damage.¹⁰

Histopathology⁵³

There is a markedly dilated follicular pore, which may extend to the mid or lower dermis. The follicle is lined by outer root sheath epithelium in which there is infundibular keratinization with the formation of keratohyaline granules. The epithelium shows acanthosis and finger-like projections that radiate into the surrounding dermis (Fig. 33.2). There is sometimes heavy melanin pigmentation of the follicular wall; pigmentation may also involve the central horny plug. The pilary unit of the involved follicle and the sebaceous gland are absent or rudimentary.

Dermoscopy of a dilated pore has shown a pinkish-white nodule, peripheral vessels whose calibers diminished with progressive branching, and a central dilated ostium containing terminal hairs.⁵⁴

PILAR SHEATH ACANTHOMA

Pilar sheath acanthoma is a rare, benign follicular tumor found almost exclusively on the upper lip of older individuals.⁵⁵⁻⁵⁷ The tumors, which measure 5–10 mm in diameter, have a central pore-like opening plugged with keratin.

Histopathology⁵⁵⁻⁵⁷

There is a central, cystically dilated follicle containing keratinous material that opens onto the surface (Fig. 33.3). Tumor lobules composed of outer root sheath epithelium extend from the wall of the cystic cavity into the adjacent dermis. Lobules sometimes reach the subcutis. Occasional abortive hair follicles may be present. The tumor epithelium shows infundibular keratinization, although it is of isthmic origin. There may be abundant glycogen in some of the tumor cells.

Differential diagnosis

The condition may be distinguished from the dilated pore of Winer, in which there is a patulous follicle with only small projections of epithelium extending into the surrounding connective tissue. In trichofolliculoma, well-formed follicles radiate from the central keratin-filled sinus and there is a well-formed stroma, which is absent in pilar sheath acanthoma.

INVERTED FOLLICULAR KERATOSIS

Inverted follicular keratosis is a benign tumor of the follicular infundibulum that was first described by Helwig in 1954. It is a somewhat controversial entity, having been regarded by some as a variant of seborrheic keratosis or verruca vulgaris.^{58,59} It occurs as a solitary flesh-colored nodular or filiform lesion that measures from 0.3 to 1 cm in diameter.⁵³ In approximately 90% of cases, the tumor occurs on the head and neck, with the cheeks and upper lip being the sites of predilection.⁵⁹ The eyelids may be involved.⁶⁰ It is more common in males and older individuals.

Lesions are successfully treated by complete excision. Although the author has seen several cases that did not recur following incomplete removal, it has been reported to recur within several weeks of an incomplete excision.⁶¹

Histopathology⁵³

Inverted follicular keratoses are predominantly endophytic tumors with large lobules or finger-like projections of tumor cells extending into the dermis. An exophytic growth pattern is present in some lesions, and it is occasionally the dominant feature. Mehregan described four growth patterns:

1. A papillomatous wart-like variant, which is largely exophytic with overlying hyperkeratosis and parakeratosis
2. A keratoacanthoma-like pattern with marginal buttress formation and a central exo-endophytic mass of solid epithelium
3. A solid nodular form, which is largely endophytic with solid, lobulated masses of epithelium
4. An uncommon cystic type, with irregular clefts within the tumor and the formation of small cysts.⁵³

Each tumor lobule is composed of basaloid and squamous cells, with the basaloid cells at the periphery and larger keratinizing cells toward the center. Mitoses are not uncommon in the basaloid cells.

A characteristic feature is the presence of squamous eddies, which are formed by concentric layers of squamous cells in a whorled pattern and which may become keratinized with the formation of keratohyalin and sometimes keratin at the center of these islands (Fig. 33.4). Sometimes, there is clefting at the periphery of the squamous eddies and even focal acantholysis. Melanin pigment is usually inconspicuous. The surrounding dermis sometimes contains a mild inflammatory cell infiltrate that is predominantly lymphohistiocytic. Telangiectatic vessels may be found in the dermal papillae in the filiform lesions.

Overlying the tumor, there is variable hyperkeratosis and parakeratosis. Funnel-shaped keratinous plugs may form. Occasionally, a prominent cutaneous horn is present.

Figure 33.3 Pilar sheath acanthoma. (A) Tumor lobules, composed of outer root sheath epithelium, radiate from a central depression. (B) The tumor lobules are composed of outer root sheath epithelium. (H&E)

Figure 33.4 (A) Inverted follicular keratosis. (B) Squamous eddies are seen toward the base of the tumor. (H&E)

Bcl-2-positive dendritic cells are present in increased numbers in the suprabasal areas of inverted follicular keratoses compared to seborrheic keratoses. This density of cells in inverted follicular keratoses correlates with the density of CD1a⁺ cells.⁶²

Dermoscopy has shown hairpin vessels, surrounded by a whitish halo, arranged radially around a white, amorphous central area. On reflectance confocal microscopy, findings are nonspecific, consisting of epidermal projections, superficial keratotic scale, and both hairpin and glomerular vessels.⁶³

Differential diagnosis

The squamous eddies of inverted follicular keratosis resemble those of irritated seborrheic keratosis; however, the endophytic configuration of the former lesion (although there may also be an exophytic component) helps to distinguish it from most seborrheic keratoses. The inverted follicular keratosis has an overall architectural resemblance to trichilemmoma, another lobulated, endophytic epithelial tumor that may be arranged about a central follicular structure. However, the latter tumors feature clear cells (due to the presence of glycogen), a distinctly palisaded basilar layer, and a surrounding cuticular basement membrane. Although a distinction between these two benign lesions per se is not generally a crucial one, recognition of trichilemmoma may be important because of its association with the

cancer-associated syndrome Cowden's disease. Human papillomavirus has not been detected in most cases, suggesting that the inverted follicular keratosis is not a variant of verruca vulgaris, as has been claimed.^{64,65} However, some cases of verruca vulgaris do develop areas with features of inverted follicular keratosis and/or trichilemmoma. In one case, pigment was increased considerably, leading to a mistaken dermoscopic and clinical diagnosis of malignant melanoma.⁶¹

TRICHOADENOMA

Trichoadenoma (of Nikolowski)⁶⁶ is a rare tumor with hair follicle-like differentiation; it is found as a nodular lesion, particularly on the face and buttocks.^{67,68} A combined trichoadenoma and intradermal nevus has been reported.⁶⁹ A trichoadenoma has developed in a mature teratoma of the ovary.⁷⁰

A lesion reported as a congenital trichoadenoma⁷¹ was regarded as a nevus sebaceus in subsequent correspondence from Ackerman.⁷²

Histopathology⁶⁷

Trichoadenoma is a well-defined dermal tumor composed of epithelial islands, most of which have a central cystic cavity containing keratinous material. The multilayered squamous epithelium shows epidermoid keratinization toward the central cavity. The appearances resemble multiple cross-sections of the infundibular portion of hair follicles (Fig. 33.5). There are no hair shafts present. Collagen fibers are present between the follicular structures. The presence of CK10 and -15 in these tumors further suggests that trichoadenoma differentiates toward the follicular infundibulum and follicular bulge regions.⁷³

Trichoadenomas contain cytokeratin 20-positive Merkel cells but lack Ber-EP4 and androgen receptor expression.⁷⁴

Verrucous trichoadenoma is a variant of trichoadenoma that clinically resembles a seborrheic keratosis.⁷⁵ It is composed of small epidermoid cysts, some of which contain vellus hairs. There is abundant keratin on the epidermal surface.⁷⁵

TRICHILEMMOMA

Trichilemmomas are small solitary asymptomatic papular lesions found almost exclusively on the face.^{10,53,76,77} Multiple trichilemmomas are a cutaneous marker of Cowden's disease (see later).

Although they appear to arise from the follicular infundibulum, they differentiate toward the outer root sheath. Ackerman regards trichilemmomas as old viral warts,^{13,78} a view not supported by most dermatopathologists^{79,80} or by immunoperoxidase studies to detect viral antigens.⁸¹

Histopathology⁸²

Trichilemmomas are sharply circumscribed tumors composed of one or more lobules that extend into the upper dermis and are in continuity with the epidermis or follicular epithelium at several points. In small lesions, follicular concentricity is apparent.⁸³ The tumor is composed of squamoid cells showing variable glycogen vacuolation, with this change being most marked deeper in the lesion (Fig. 33.6). Centrally, there may be foci of epidermal keratinization and occasionally small squamous eddies. Keratinous microcysts may form in large lesions. There is a peripheral layer of columnar cells with nuclear palisading resembling the outer root sheath of hair follicles. A thickened glassy basement membrane surrounds the tumor in part (Fig. 33.7). This is periodic acid–Schiff (PAS) positive and diastase resistant. The stroma is occasionally hyalinized or desmoplastic.^{77,84} The term '*desmoplastic trichilemmoma*' is used for this histological variant (Fig. 33.8). A case of desmoplastic trichilemmoma arising in an organoid

Figure 33.5 (A) Trichoadenoma. (B) There are multiple 'cystic structures' resembling cross-sections of the infundibular portion of hair follicles. (H&E)

nevus has been reported.⁸⁵ Another case, on the eyelid, was misdiagnosed as sebaceous carcinoma.⁸⁶

The overlying epidermis shows hyperkeratosis, mild acanthosis, and sometimes a prominent granular layer. Uncommonly, a cutaneous horn will form (*trichilemmomal horn*).⁸⁷ This differs from the *trichilemmal horn*, in which a horn showing trichilemmal keratinization overlies a depression in the epidermis that usually has a prominent basement membrane.⁸⁸ Warts, basal and squamous cell carcinomas, and inverted follicular keratoses and seborrheic keratoses sometimes contain areas of trichilemmal differentiation.^{78,89}

CD34 has been reported in trichilemmomas and also in the external root sheath of normal hair follicles.⁹⁰ Its presence in desmoplastic trichilemmoma may be of diagnostic value; it is not present in basal cell carcinoma⁹¹ or sebaceous carcinoma.⁸⁶ The cytokeratin expression of trichilemmomas has been studied.⁹² CK1 and CK10 are present in keratinizing ductal epithelium. CK14 is present in the whole layer, whereas CK16 is present in the suprabasal layer but absent in keratinizing ductal epithelium.⁹²

Differential diagnosis

The differential diagnosis of trichilemmoma includes other tumors with clear cell variants, including basal cell carcinoma and squamous cell carcinoma. The greater degrees of atypia in those two lesions

Figure 33.6 (A) Trichilemmoma. (B) Vacuolation of the tumor cells near the base of the lesion is marked. (H&E)

Figure 33.7 Trichilemmoma. Vacuolization creates a clear cell appearance. Note the thickened, cuticular basement membrane (arrows). (H&E)

Figure 33.8 Desmoplastic trichilemmoma. The lesion has a pseudo-infiltrative configuration, with groups and cords of epithelial cells that appear to be 'disrupted' by fibromyxoid connective tissue. (H&E)

should ordinarily allow distinction, and the CD34 positivity of trichilemmoma may also constitute a distinguishing feature. However, a variant of basal cell carcinoma has been described with thickened basement membrane, capable of mimicking trichilemmoma and other benign tumors.⁹³ In addition, basal cell carcinoma has been reported to arise in association with desmoplastic trichilemmomas.⁹⁴ Inverted follicular keratosis has an endophytic, lobulated growth arrangement similar to that of trichilemmoma, and in fact the two are often discussed together as benign, lobulated verruciform lesions. However, the inverted follicular keratosis has a closer resemblance to the irritated seborrheic keratosis and is often considered an endophytic variant of that lesion. Accordingly, there are usually horn cysts and some degree of intercellular edema (spongiosis), whereas the distinctive peripheral palisading and cuticular basement membrane of trichilemmoma are not apparent. As previously mentioned, neither trichilemmoma nor inverted follicular keratosis has been shown to contain the DNA of human papillomavirus. Mutation of the phosphatase and tensin homolog (*PTEN*) gene is a feature of Cowden's disease (see later), and accordingly, expression of the tumor suppressor protein, *PTEN*, has been found to be reduced or absent in trichilemmomas from patients with Cowden's disease. However, a recent study showed that *PTEN* staining is also reduced in 13.5% of sporadic trichilemmomas,⁹⁵ suggesting that, in an individual case, *PTEN* staining reduction in this tumor cannot be used as *prima facie* evidence that that patient also has Cowden's disease. Desmoplastic trichilemmomas can mimic invasive carcinomas due to the interdigitation of islands of epithelial cells with fibromyxoid connective tissue. However, a distinction can usually be made because desmoplastic trichilemmomas have good overall lesional circumscription; confinement of desmoplastic changes to the central portion of the tumor; CD34 positivity; and a lack of squamous differentiation, basaloid foci, or significant cytologic atypia.^{96,97}

COWDEN'S DISEASE

Cowden's disease (Cowden's syndrome, *PTEN* hamartoma tumor syndrome, multiple hamartoma and neoplasia syndrome; OMIM 158350) is a rare multisystem condition with autosomal dominant inheritance.^{98–102} The eponym is the surname of the propositor of the report by Lloyd and Dennis in 1963.¹⁰³ The mucocutaneous features

are the most constant findings. These include multiple trichilemmomas,¹⁰⁴ which are usually on the face, acral keratoses, palmar pits, and mucocutaneous papillomatous papules.^{99,105} They usually appear in late adolescence. The tumor of the follicular infundibulum may also arise in Cowden's disease.¹⁰⁶ Multiple inverted follicular keratoses were present in one affected person.¹⁰⁷ There is also a high incidence of visceral hamartomas and tumors, including fibrocystic disease of the breast,¹⁰⁸ thyroid adenomas, ovarian cysts, subcutaneous lipomas and neuromas, gastrointestinal polyps,¹⁰⁹ and carcinomas of the breast and thyroid.¹⁰¹ Also documented are eye changes;¹¹⁰ skeletal abnormalities;¹¹¹ acromelanosis;¹¹⁰ non-Hodgkin's lymphoma;¹⁰⁴ and carcinomas of the skin, tongue,¹¹² testis,¹¹³ and cervix. Impaired T-cell function has been reported in this syndrome.¹¹¹ Intestinal ganglioneuromatosis has been reported in a recent case.¹¹⁴

Cowden's disease involves a mutation in the *PTEN* gene on chromosome 10q23.31 (10q22–q23), a tumor suppressor gene with tyrosine phosphatase and tensin homology.^{115–117} A similar genetic abnormality occurs in the Bannayan–Zonana syndrome, suggesting that they are different phenotypic expressions of the one disease.¹¹⁸ This syndrome has also been reported as the Bannayan–Riley–Ruvalcaba syndrome (OMIM 153480), its preferred name,^{119–121} and the Ruvalcaba–Myre syndrome.¹¹⁸ Macrocephaly, genital lentiginosis, and lipomatosis are the hallmarks of this syndrome.¹²² It may present with trichilemmomas and lipomas. Germline mutations in the *PTEN* gene have been found in 65% of individuals with this syndrome and in 85% of individuals with classic Cowden's disease.¹²¹ It is thought that the rest may harbor pathogenic variants that have escaped detection by standard methodologies.¹²³ Lhermitte–Duclos disease (OMIM 158350) also has mutations in the *PTEN* gene. It may present with cerebellar ataxia and other manifestations of Cowden's disease.^{124,125} A Proteus-like syndrome has also been reported,^{126,127} as have autism spectrum disorders associated with macrocephaly. The term **PTEN hamartoma tumor syndrome** has been applied to this entire spectrum of disorders.¹²⁸

The pathogenesis of malignant tumors in Cowden's disease appears to require complete inactivation of the *PTEN* gene.¹²⁹ Analysis of the trichilemmomas in this disease shows loss of heterozygosity at the *PTEN* locus.¹³⁰

Histopathology^{131–134}

Most of the facial lesions are trichilemmomas or tumors of the follicular infundibulum. The trichilemmomas are cylindrical or lobular in configuration.¹³¹ Sometimes the lesions keratinize with squamous eddies, resembling an inverted follicular keratosis. Nonspecific verrucous acanthomas and lesions resembling digitate warts may also be present.¹³¹

The extrafacial lesions are mostly hyperkeratotic papillomas that resemble verruca vulgaris, acrokeratosis verruciformis, or a non-descript hyperkeratotic acanthoma.¹³² This latter change may take the form of hyperplasia of the follicular infundibulum.¹³² No evidence of a viral etiology has been found on electron microscopy^{111,135} or with immunoperoxidase studies.

Distinctive dermal fibromas (sclerotic fibromas) with interwoven fascicles of coarse collagen, sometimes showing marked hyalinization, are not uncommon in Cowden's disease.^{132,136} They may have a plywood-like appearance histologically (see p. 974).

TUMOR OF THE FOLLICULAR INFUNDIBULUM

Despite its name, the tumor of the follicular infundibulum is really of isthmic origin.¹³⁷ It usually occurs as a solitary, asymptomatic, smooth or slightly keratotic papule on the head and neck or upper chest.⁵³ Multiple lesions, including a mantle distribution on the upper trunk (infundibulomatosis, eruptive infundibulomas),^{138,139} have been reported.¹⁴⁰ The tumor of the follicular infundibulum may also occur

Figure 33.9 Tumor of the follicular infundibulum. There is a plate-like subepidermal tumor with multiple connections to the undersurface of the epidermis. The island on the left side of the figure contains clear cells and is surrounded by a cuticular basement membrane, resembling trichilemmoma. (H&E)

in Cowden's disease, the Schöpf–Schultz–Passarge syndrome, and in an organoid nevus.¹⁰⁶ It has been reported coexisting with an unusual trichilemmal tumor, which had some resemblance to a desmoplastic trichilemmoma.¹⁴¹

The treatment of this tumor is usually a 'watch and wait' approach with long-term supervision. Symptomatic tumors have been treated with salicylic acid, etretinate, and cryotherapy, with only slight improvement.¹⁴²

Histopathology⁵³

The growth pattern resembles that of a superficial basal cell carcinoma. There is a plate-like fenestrated subepidermal tumor composed of pale or pink-staining glycogen-containing cells, with a peripheral palisade of basal cells. Some of the cords are basaloid without pale-staining cytoplasm. The tumor connects at intervals with the undersurface of the epidermis by slender pedicles (Fig. 33.9). Hair follicles entering the tumor from below lose their identity and merge with it. Small follicular bulbs and papillary mesenchymal bodies may be found. Focal sebaceous differentiation is rare.^{143,144} Ductal structures, resembling eccrine ducts, have been reported in the tumor strands.¹⁴⁵ The surrounding loose connective tissue stroma contains a network of elastic fibers.^{53,138} The histological features sometimes overlap those of trichilemmoma, but the low-power architecture is quite different.

The tumor of the follicular infundibulum appears to be the same as that reported as a basal cell hamartoma with follicular differentiation.¹⁴⁶ However, it is histologically dissimilar to the cases reported as **multiple infundibular tumors of the head and neck**.¹⁴⁷ In these latter cases, clusters of enlarged follicular infundibula comprised each lesion, somewhat similar to the appearances of prurigo nodularis. The illustrations in the report of a tumor called an **infundibular keratosis** showed some features of the multiple infundibular tumor referred to previously and others of an inverted follicular keratosis (see later) but without squamous eddies.¹⁴⁸

OUTER ROOT SHEATH ACANTHOMA

The term 'outer root sheath acanthoma' has been used for a distinctive tumor that developed on the cheek of an 80-year-old male.¹⁴⁹ On lower power, it has some features of the tumor of the follicular infundibulum with anastomosing columns of cells on the undersurface of the

epidermis. With progressive descent into the dermis, the tumor cells show outer root sheath differentiation characteristic of the infundibulum, isthmus, stem, and anagen bulb.¹⁴⁹

BENIGN FOLLICULAR NEOPLASMS WITH GERMINATIVE-TYPE DIFFERENTIATION

TRICHOFOLLICULOMA

Trichofolliculoma is a rare pilar tumor, intermediate in differentiation between a hair follicle nevus and a trichoepithelioma (see later). It usually presents as a solitary tumor, approximately 0.5 cm in diameter, on the head and neck, usually the face.¹⁵⁰ A tuft of fine hairs may protrude from a central umbilication. A collision tumor of trichofolliculoma and basal cell carcinoma has been reported.¹⁵¹

Schulz and Hartschuh published their detailed observations on the evolution of a trichofolliculoma.¹⁵² They suggest that the trichofolliculoma undergoes changes corresponding to the regressing hair follicle in its well-known cycle.¹⁵² There is evidence that trichofolliculoma differentiates toward the hair bulge and the isthmus outer root sheath.¹⁵³ Studies in transgenic mice show that blockage of bone morphogenic protein (BMP) signaling (BMP is one of the signaling molecules implicated in normal hair follicle differentiation) results in hair follicle neoplasias that resemble human trichofolliculoma.¹⁵⁴

Histopathology^{10,11,150}

There are one or several dilated follicles from which radiate numerous small follicles of varying degrees of maturity (Fig. 33.10). The central follicle, which opens onto the surface, usually contains keratinous material and sometimes vellus hairs. The follicles that branch off the central follicle may in turn give rise to secondary or even tertiary follicles. Sometimes only rudimentary pilar structures or epithelial cords are formed. In older lesions, catagen and telogen follicles are present.¹⁵² Trichofolliculomas have a relatively cellular connective tissue stroma. This complex pattern is quite different from the hair follicle nevus (discussed previously), which is composed of mature vellus follicles. Merkel cells are found in the outer sheath of the small follicles.¹⁵⁵

Scattered vacuolated cells representing sebaceous differentiation may be present within the follicles or the rudimentary structures. Sebocytes are seen more often in late-stage lesions. Epidermolytic hyperkeratosis has been found as an incidental change.¹⁵⁶ A variant of trichofolliculoma in which large sebaceous follicles connect to a central cavity or sinus has been reported as a **sebaceous trichofolliculoma**.¹⁵⁷ It has some similarities to the folliculosebaceous cystic hamartoma (see p. 924), which appears to be a trichofolliculoma at a late stage in its evolution.^{152,158,159}

The secondary follicles in trichofolliculoma express CK14 but not CK1 and CK10. CK15 is present in the basal layers.¹⁶⁰

TRICHOEPITHELIOMA

Trichoepitheliomas (trichoblastomas in the classification of Ackerman *et al.*) are regarded as poorly differentiated hamartomas of hair germ.^{10,13} There are three variants of trichoepithelioma: solitary, multiple, and desmoplastic. The histological features of the solitary and multiple types are identical, and they are considered together. Desmoplastic trichoepithelioma is a distinct clinicopathological entity, and it is discussed separately.

Solitary trichoepitheliomas are found as skin-colored papules, with a predilection for the nose, upper lip, and cheeks. They measure up to 0.5 cm in diameter. Most of the lesions reported as giant solitary trichoepitheliomas are trichoblastomas.^{161–164} Rare presentations include

Figure 33.10 (A) Trichofolliculoma. (B) Small follicles with variable maturity radiate from a larger central follicle. (H&E)

a linear form and as a large, hemifacial plaque.^{165,166} Vulvar trichogenic tumors can be misdiagnosed as basal cell carcinomas, leading to overtreatment.¹⁶⁷

Multiple familial trichoepitheliomas (epithelioma adenoides cysticum; OMIM 601606) have an autosomal dominant mode of inheritance, with lessened expressivity and penetrance in the male. It is due to a mutation in the *CYLD* (cylindromatosis) gene on chromosome 16q12–q13.^{168,169} Mutations in this gene may also produce familial cylindromatosis (OMIM 132700) and the Brooke–Spiegler syndrome (multiple trichoepitheliomas and cylindromas; OMIM 605041).^{168,170–174} The presence also of spiradenomas may be another manifestation of Brooke–Spiegler syndrome.¹⁷⁵ These various manifestations have been regarded as different expressions of a folliculosebaceous–apocrine genodermatosis.¹⁷⁶ Multiple different mutations in this gene have been reported in familial trichoepitheliomas.^{168,177} The gene encodes the protein CYLD, which is a deubiquitinating enzyme implicated in modulation of the nuclear factor (NF)- κ B pathway.¹⁶⁸ It is downregulated, or not expressed as a result of the gene mutations.¹⁷⁸ The significance of the much earlier report implicating 9p21 in multiple trichoepitheliomas is uncertain.¹⁷¹ Sporadic cases of this condition also occur.^{10,179} Multiple trichoepitheliomas present as small papules with a strong predilection for the central part of the face.¹⁸⁰ The trunk, neck, and scalp are sometimes involved. The papules may coalesce to give plaques.^{181–184} The onset of lesions is usually in childhood or at the time

of puberty.¹⁸⁵ Rare presentations include a linear and dermatomal distribution,¹⁸⁶ linear lesions on the face in the lines of Blaschko (a possible type 2 segmental manifestation),^{187,188} development in an epidermal nevus,¹⁸⁹ an association with cylindromas (Brooke–Spiegler syndrome)^{182,190} and sometimes also with spiradenomas (discussed previously),^{175,176,191} and an association with ungual fibromas,¹⁹² dystrophia unguis congenita,¹⁹³ and the ROMBO syndrome (verrucate atrophoderma, milia, hypotrichosis, trichoepithelioma, basal cell carcinomas, and peripheral vasodilatation).^{194–196} A *PTCH* gene deletion was present in the trichoepitheliomas that developed in a patient with neurofibromatosis (NF-1).¹⁹⁷ The simultaneous appearance of trichoepitheliomas and carcinoma of the breast has also been reported.¹⁹⁸

Trichoepitheliomas are benign lesions. Many of the cases of malignant transformation reported in the older literature represent cases of the nevoid basal cell carcinoma syndrome and not trichoepitheliomas.¹⁰ Nevertheless, there are several documented cases of basal cell carcinoma developing in trichoepithelioma^{199–201} and one case of a malignant tumor, with pilar (including matrical) differentiation, arising in a trichoepithelioma.²⁰²

One study has shown deletions at 9q22.3 (the location of the *patched* (*PTCH*) gene of the basal cell nevus syndrome) in sporadic trichoepitheliomas.²⁰³

Various treatment modalities have been successful in treating trichoepithelioma,²⁰⁴ including carbon dioxide laser vaporization,²⁰⁵ cryotherapy, electrosurgery, surgical excision, and radiotherapy.²⁰⁴ For multiple trichoepitheliomas, additional treatment methods have included argon laser and the combination of erbium:YAG and CO₂ laser.²⁰⁶ Such therapies pose an important risk of significant scarring in the area affected.¹⁸⁴ Very gradual improvement has been reported following the use of aspirin and subcutaneous adalimumab to block tumor necrosis factor activation of NF- κ B at two levels of the pathway.²⁰⁷

Histopathology

Trichoepitheliomas are dermal tumors with focal continuity with the epidermis in up to one-third of cases. They are composed of islands of uniform basaloid cells, sometimes showing peripheral palisading. This may lead to a mistaken diagnosis of basal cell carcinoma if features of pilar differentiation are not noted. In addition, there are usually branching nests of basaloid cells. Epithelial structures resembling hair papillae or abortive hair follicles may be seen (Fig. 33.11). A tumor with giant and multinucleated epithelial cells has been reported.²⁰⁸ Small keratinous cysts lined by stratified squamous epithelium are quite common. Rupture of these cysts with liberation of the keratinous debris results in a small foreign body granuloma in the stroma. Foci of calcification are often present; amyloid is generally considered to be uncommon, although it was present in 33% of cases in one study.^{209,210} Melanocytes are common in most pilar neoplasms.²¹¹ The stroma is prominent and loosely arranged. Aggregations of fibroblasts, representing abortive attempts to form papillary mesenchyme (papillary mesenchymal bodies), are characteristic of trichoepithelioma.²¹² A trichoepithelioma with ‘monster’ stromal cells resembling an atypical fibroxanthoma has been reported.²¹³ A trichoepithelioma-like basal cell carcinoma has also been documented.²¹⁴ LeBoit has editorialized on the morphological overlap of these two tumors.²¹⁵

Immunohistochemical staining of trichoepitheliomas resembles that seen in the outer root sheath, with strong reactions for cytokeratins (CK) 5/6 and CK8. Some CK17 is present in cells surrounding horn cysts.²¹⁶

Electron microscopy

In trichoepitheliomas, there is a proliferation of basaloid cells similar to basal cell carcinoma.²¹⁷ Abortive hair papillae and keratinous cysts may be seen. The cells sometimes contain paranuclear glycogen, a feature not seen in basal cell carcinomas.²¹⁷

Figure 33.11 (A) Trichoepithelioma. There are multiple nests of basaloid cells, with some showing abortive hair follicle differentiation. **(B)** Early follicular stromal induction is present. (H&E)

DESMOPLASTIC TRICHOEPITHELIOMA

Desmoplastic trichoepithelioma is a histological variant of trichoepithelioma that occurs almost exclusively on the face.^{218–225} There is a predilection for females and relatively young adults. A congenital example has been reported.²²⁶ Solitary familial desmoplastic trichoepithelioma^{218,227} and multiple familial^{228,229} and nonfamilial tumors²¹⁹ have been reported. Desmoplastic trichoepitheliomas usually present as asymptomatic solitary hard annular lesions with a raised border and a depressed center. They vary from 3 to 8 mm in diameter. Atypical clinical presentations have been reported.²³⁰

The finding of Merkel cells as an integral constituent of this tumor raises the possibility of a bulge-derived origin because of the high number of Merkel cells known to reside in this area of the follicle.²³¹

Histopathology²³²

Desmoplastic trichoepitheliomas are reasonably well-circumscribed tumors in the upper and mid dermis, with an overlying central depression. They are composed of cords and small nests of basaloid cells with

Figure 33.12 (A) Desmoplastic trichoepithelioma. (B) It is composed of small cords and islands of basaloid cells set in a fibrous stroma. Small keratinous cysts are also present. (H&E)

scanty cytoplasm (**Fig. 33.12**). Tumor strands may be attached to the epidermis. There are usually many keratinous (horn) cysts, with a peripheral basaloid layer and several layers of stratified squamous epithelium with central loosely laminated horn.²³³ Sometimes this epithelial lining is attenuated and one cell thick. Perineural involvement by cords of tumor is an unusual feature that has been occasionally noted in desmoplastic trichoepithelioma; however, this should not be taken as a sign of malignancy because these tumors have a biologic course similar to that of other trichoepitheliomas without this finding, and recurrences have not been reported.^{234,235}

The desmoplastic stroma is dense and hypocellular, with fewer elastic fibers and more acid mucopolysaccharides than in the normal dermis. Other features that are frequently present include foreign body granulomas, usually related to ruptured cysts, and calcification. Stromal ossification is rare. Occasionally, foci of sebaceous cells or shadow cells are present. Rarely, a nevocellular nevus is also present,^{220,236} and an association with cellular blue nevus has also been described.²³⁷

The cord-like basaloid cells in desmoplastic trichoepitheliomas express CK1/5/10/14, CK5/8, CK14, and CK15 but not CK6.²³⁸

Electron microscopy

Ultrastructural studies^{218,223} have shown basaloid cells surrounded by a basal lamina. Individual cells contain tonofilaments and are connected to adjacent cells by desmosomes.

Differential diagnosis of trichoepithelioma and desmoplastic trichoepithelioma

Solitary and multiple trichofolliculoma

Conflicting views have been expressed on the specificity of cyto-keratin types in the distinction between trichoepithelioma and trichoblastoma. Although one study concluded that there were no differences,²³⁹ another study found CK7 in trichoblastomas but not trichoepithelioma.²⁴⁰

The chief differential diagnostic consideration when evaluating for possible trichoepithelioma is basal cell carcinoma. In contrast to trichoepithelioma, basal cell carcinoma is more apt to feature a fibromyxoid stroma, clefting artifact separating tumor islands from this adjacent stroma, and apoptotic foci in the presence of melanin deposition. On the other hand, trichoepitheliomas more often feature papillary mesenchymal bodies, although these can be seen occasionally in basal cell carcinomas with follicular differentiation ('keratotic' basal cell carcinomas). Numerous studies have endeavored to find ways to distinguish trichoepithelioma from basal cell carcinomas using special stains and immunohistochemical methods. Thus, basal cell carcinomas are said to contain more elastic fibers than trichoepitheliomas.²⁴¹ Trichoepitheliomas express CK15, whereas only a subset of basal cell carcinomas do so.²⁴² Basal cell carcinomas differ from trichoepitheliomas by having stronger and more diffuse expression of proliferating cell nuclear antigen (PCNA) and Ki-67.²⁴³ They also show greater expression of p53 than do trichoepitheliomas.²⁴⁴ CD10 expression varies, but a small number of cases show overlap features. As a rule, trichoepithelioma shows CD10 stromal immunoreactivity, whereas in basal cell carcinoma the staining involves basaloid cells, but some stromal staining is sometimes seen.²⁴⁵ Both basal cell carcinomas and trichoepitheliomas express p27^{kip1}, but staining tends to be patchy in trichoepithelioma and more diffuse in basal cell carcinoma.²⁴⁶ Peritumoral stromal cells expressing CD34 are almost invariably present in pilar tumors such as trichoepithelioma.²¹¹ Drebin, an F-actin binding protein involved in cell migration, shows strong expression in cell-cell boundaries in basal cell carcinomas but weak, nonhomogeneous expression in trichoepitheliomas and trichoblastomas.²⁴⁷ In a recent study using tissue microarrays and a panel of antibodies that included CD10, CD34, epithelial membrane antigen (EMA), bcl-2, CK15, CK20, and D2-40, investigators concluded that there is overlap of both epithelial and stromal staining profiles, suggesting that these tumors represent two points in a spectrum of differentiation of a single cell type and that clinical and histopathologic criteria remain the best methods for differential diagnosis.²⁴⁸

Two other adnexal tumors that bear a passing resemblance to classic trichoepithelioma are cylindroma and spiradenoma, both thought to display sweat gland differentiation. Both of these lesions show much more intercellular basement membrane material. Cylindroma features mucin-containing cylinders of cells, whereas spiradenoma shows internal dispersion of mature lymphocytes and prominent lymphatic spaces.

Desmoplastic trichoepithelioma

The major differential diagnostic considerations for desmoplastic trichoepithelioma include syringoma, infiltrative/morpheaform basal cell carcinoma, and microcystic adnexal carcinoma.^{224,233,249} The distinction from syringoma is most difficult in thin shave biopsies, when only a portion of the lesion can be visualized and circumscription and lesional depth cannot be appreciated. Unfortunately, tadpole- or comma-shaped epithelial projections, features associated with syringomas,

extend from the peripheral layer of some of the keratinous cysts in trichoepithelioma, and occasionally structures resembling eccrine ducts are also present. On the other hand, syringomas rarely have horn cysts, foreign body granulomas, or calcification.²³² Narrow strands of tumor cells are also unusual in syringomas. Furthermore, syringomas are frequently periorbital and multiple in that location. The tumor cells of trichoepithelioma do not contain carcinoembryonic antigen, unlike the cells in a syringoma, which are usually positive.²²¹ In contrast, involucrin is expressed in desmoplastic trichoepitheliomas but not in syringomas.²²²

Basal cell carcinomas of morpheaform type may form clefts between the nests and the stroma.²²⁴ Mitoses and apoptotic bodies are also quite common in basal cell carcinomas, whereas foreign body granulomas and ruptured keratinous cysts are uncommon.²²⁴ In contrast to morpheaform basal cell carcinoma, the desmoplastic trichoepithelioma is better circumscribed both laterally and at its base, lacks a fibromucinous stroma, and does not contain macronodular foci, which are frequently present in morpheaform basal cell carcinoma.²⁵⁰ Nevertheless, the morphologic overlap of desmoplastic trichoepithelioma and morpheaform basal cell carcinoma has led to a vigorous search for immunohistochemical markers that might reliably distinguish between the two. The staining pattern for CD34 and bcl-2 is of use in the differentiation of these two tumors. The spindle-shaped cells surrounding the cellular islands in desmoplastic trichoepithelioma are focally strongly positive for CD34, whereas the stromal cells around basal cell carcinomas are usually negative.^{251–253} As is the case in basal cell carcinoma, EMA is negative in desmoplastic trichoepitheliomas.²¹⁴ Whereas bcl-2 is expressed in most basal cell carcinomas, it is found only in the basal layer of trichoepitheliomas. Ber-EP4 is positive at least focally in most trichoepitheliomas, contrasting with the usual diffuse staining in basal cell carcinoma.²¹⁴ Up to 80% of basal cell carcinomas express androgen receptors, whereas trichoepitheliomas are typically negative.^{254–257} Merkel cells (CK20⁺) are present in desmoplastic trichoepitheliomas but uncommon in basal cell carcinomas.^{254,258} Unfortunately, these markers do not always differentiate reliably between basal cell carcinoma and desmoplastic trichoepithelioma because Merkel cells are sometimes sparse in desmoplastic trichoepitheliomas.^{255,256,259} As noted in Chapter 31 in the discussion of basal cell carcinoma, fibroblast-activation protein may be useful in differentiating between these tumors because positive staining is observed in the peritumoral stromal fibroblasts of infiltrative/morpheaform basal cell carcinoma and not in desmoplastic trichoepithelioma.²⁶⁰ Also as discussed in that section, p75 neutrophin receptor stains the tumor islands of desmoplastic trichoepithelioma and, generally, not those of morpheaform basal cell carcinoma.²⁶¹ Unfortunately, occasional exceptions, in which morpheaform basal cell carcinomas express this marker, reduce its practical value in differential diagnosis.²⁶² The hair bulge marker PHLDA1 may be useful because it appears to reliably differentiate between trichoepithelioma, including desmoplastic trichoepithelioma (positive staining), and basal cell carcinoma (negative staining, except for tumor islands in close proximity to ulcers).^{263,264} Another study examining PHLDA1 expression seems to have generally confirmed this finding, although 12% of cases of morpheaform basal cell carcinoma showed staining in up to one-fourth of tumor cells and a similar percentage of desmoplastic trichoepitheliomas did not demonstrate strong staining in more than half of tumor cells.²⁶⁵

The distinction of desmoplastic trichoepithelioma from microcystic adnexal carcinoma can be quite difficult or impossible, particularly when superficial shave biopsies are submitted for evaluation. However, the latter consists of more tubular cell nests, and deeper biopsy shows that infiltrating cellular islands permeate deeply into the subcutaneous tissue and are prone to perineural infiltration. As is the case for basal cell carcinoma, but not for desmoplastic trichoepithelioma, stromal cells around microcystic adnexal carcinoma are usually CD34⁺. Sellheyer *et al.* developed an immunohistochemical algorithm for

distinguishing among desmoplastic trichoepithelioma, morpheaform basal cell carcinoma, and microcystic adnexal carcinoma.²⁶⁶ This system begins with BerEP4. *Positive* staining could mean either desmoplastic trichoepithelioma or basal cell carcinoma. If staining is positive for PHLDA1, desmoplastic trichoepithelioma is the likely diagnosis and would be expected to be CK15⁺ and CK19⁻; if staining is negative for PHLDA1, basal cell carcinoma would be the likely diagnosis and could be CK15⁺ or -15⁻ and CK19⁺ or -19⁻. *Negative* staining for BerEP4 could mean either microcystic adnexal carcinoma or desmoplastic trichoepithelioma. If staining is then positive for PHLDA1, the choices would be either microcystic adnexal carcinoma or desmoplastic trichoepithelioma; CK15⁺ and CK19⁻ would again favor desmoplastic trichoepithelioma, with the reverse result indicating microcystic adnexal carcinoma. If staining is negative for PHLDA1, microcystic adnexal carcinoma would be the likely diagnosis.²⁶⁶ Another recent study confirms the adjunctive value of CK19 in the differential diagnosis between desmoplastic trichoepithelioma and microcystic adnexal carcinoma because most examples of the former are negative for this marker, whereas most microcystic adnexal carcinoma cases are CK19⁺.²⁶⁷ In all studied cases, CK17 and epidermal growth factor receptor expression were positive in both of these tumors.²⁶⁷

PILOMATRICOMA

In this group, there is differentiation toward cells of the hair matrix and hair cortex and cells of the inner sheath. The prototype tumor is the pilomatricoma. A rare malignant variant, the pilomatrix carcinoma, has also been described. A solitary case of 'pilomatrical carcinosarcoma' was reported in 1994.²⁶⁸ Matrical differentiation can also be seen in other tumors:

- Melanocytic matricoma (see later)
- Epidermal cyst
- Trichoblastoma²⁶⁹
- Trichoepithelioma
- Panfolliculoma
- Basal cell carcinoma
- Apocrine mixed tumor
- Complex adnexal tumors.

Pilomatricoma (pilomatrixoma, calcifying epithelioma of Malherbe; OMIM 132600), which accounts for almost 20% of pilar tumors, is a benign lesion with differentiation toward the matrix of the hair follicle.²⁷⁰ It is found particularly on the head and neck and upper extremities.^{11,271} A case has arisen in a bacillus Calmette–Guérin vaccination site.²⁷² Approximately 60% develop in the first two decades of life.^{273,274} They are mostly solitary, but multiple lesions – usually less than five in total – are sometimes found.^{275–279} Some patients with multiple lesions have myotonic dystrophy.^{11,280–282} They have also been reported in Turner's syndrome,²⁸³ trisomy 9,²⁸⁴ Sotos syndrome (cerebral gigantism; OMIM 117550),²⁸⁵ and with other abnormalities.^{286–288} A familial occurrence is rarely noted.^{289,290} A pilomatricoma-like change is not uncommon in the epidermal cysts found in Gardner's syndrome.²⁹¹ This syndrome has also been described in a patient with multiple pilomatricomas.²⁹²

Pilomatricomas are firm nodules, approximately 0.5–3.0 cm in diameter. A recently described diagnostic sign, the 'skin crease sign', can be elicited in pilomatricomas: when a lesion is squeezed lightly with the thumbs, especially when squeezed perpendicularly to the skin tension lines, a central longitudinal crease is seen within the lesion.²⁹³ Exophytic and giant forms have been recorded.^{294–297} One such giant lesion was associated with hypercalcemia and elevated levels of parathyroid hormone-related protein that returned to normal after removal of the tumor.²⁹⁸ Overlying striae and anetodermic changes have been reported in a few cases.^{299–302} A bullous (lymphangiectatic) variant

related to superficial lymphangiectasia has been reported.^{303–305} Anetodermic pilomatricomas have surface changes that have been described as wrinkled or keloidal as well as bullous in appearance.³⁰⁶ Pilomatricomas are usually slow growing, but rapid enlargement due to hemorrhage has been reported.³⁰⁷ Rarely, there is sufficient melanin pigment in the lesion to be visible clinically.³⁰⁸ These tumors have a variegated appearance macroscopically, with gray, white, and brown areas on the cut surface. Small spicules of bone and minute thorny fragments may be discernible.³⁰⁹ The consistency of the nodules depends on the amount of calcification and ossification. Multinodular variants are rare.³¹⁰

Activating mutations in β -catenin, a constituent of the adherens junctions, have been found in sporadic pilomatricomas.^{311–314} A similar defect is also found in colonic carcinomas.³¹¹ The β -catenin gene (*CTNNB1*) maps to chromosome 3p22–p21.3. Trisomy 18 has been regularly demonstrated in a subset of cells in the basal epithelial cell component of pilomatricoma.³¹⁵ Among the genes carried on this chromosome is *BCL-2*, encoding the anti-apoptotic protein. Overexpression of *bcl-2* has been found in a variety of tumors, and it may play a role in the development and differentiation of pilomatricoma.³¹⁵

Most tumors, even if inadequately excised, will not recur. However, local recurrence and aggressive forms have been documented.^{316,317} The malignant variant, pilomatrix carcinoma, is discussed later.

Surgical excision is the usual method of treatment. The author has seen numerous incompletely excised lesions that have not recurred and several that have. Recurrence does not seem to occur in ‘burnt-out’ lesions devoid of a basaloid component.

Histopathology

The appearances vary according to the age of the lesion. Established lesions are sharply demarcated tumors in the lower dermis, extending quite often into the subcutis. There are masses of epithelial cells of various shapes, with an intervening connective tissue stroma containing blood vessels, a mixed inflammatory cell infiltrate, foreign body giant cells, and sometimes hemosiderin, melanin, bone, and rarely amyloid.^{10,318}

There are two basic cell types – basophilic cells and eosinophilic shadow cells (Fig. 33.13). The basophilic cells tend to be at the periphery of the cell islands and have little cytoplasm, indistinct cell borders, hyperchromatic nuclei, and plentiful mitoses. They resemble the cells of a basal cell carcinoma. They are sometimes the predominant cell in lesions removed from elderly patients. The term ‘*proliferating pilomatricoma*’ has been proposed for this variant (Fig. 33.14).^{319,320} Occasional examples of proliferating pilomatricoma have been reported in young people.³²¹ Follicular germinative cells have been reported in a palisaded arrangement at the edges of collections of matrical cells in cases of pilomatricoma.³²² The eosinophilic shadow cells in the usual form are found toward the central areas of the cell masses. They have more cytoplasm and distinct cell borders but no nuclear staining. These shadow (mummified) cells form from the basophilic cells, and the transition may be relatively abrupt or occur over several layers of cells (transitional cells). The intermediary cells develop progressively more eosinophilic cytoplasm, and the nucleus becomes pyknotic. The mode of cell death has been reported as apoptotic,^{323,324} but it is more likely that the shadow cells represent terminal differentiation rather than apoptosis.^{325,326} Hyalinization of the cells, squamous change, or disruption into amorphous debris may result. Pigmented variants display dendritic melanocytes among basophilic cells with some pigment transfer to the cytoplasm of those cells; occasionally, melanin pigment can also be found in shadow cells.³²⁷

Calcification occurs in more than two-thirds of the tumors and is usually in the shadow cells. Ossification of the stroma occurs in approximately 13%;³²⁸ hemosiderin is found in approximately 25% of cases;³²⁹ and melanin is present in nearly 20% of lesions and may be in the

Figure 33.13 (A) Pilomatricoma. (B) There are two cell types present – nests of basaloid cells and shadow cells. The lesion is partly cystic. (H&E)

Figure 33.14 Pilomatricoma of proliferating type. Mitotic figures can be seen. (H&E)

shadow cells as well as in the stroma.^{329,330} Extramedullary hematopoiesis may occur adjacent to the spicules of bone.³³¹ BMP-2, which plays an important role in ectopic bone formation, has been found in the shadow cells, suggesting that it may play a role in generating bone formation in pilomatricomas.³³² It results in the deposition of type II collagen at the dermoepidermal junction.³³³ Dendritic cells are sometimes seen among the basophilic cells in the cases with pigmentation.

The bullous (lymphangiectatic) lesions have marked dilatation of superficial lymphatics overlying the tumor.^{303,334} There may be some loss of elastic fibers, as seen in the anetodermic variant and best displayed with Verhoeff–van Gieson or other elastic tissue stains.^{301,305,306,335} The surrounding dermis may be edematous in these bullous variants.³⁰⁵ It is believed that anetoderma and accompanying changes are due to the effects of mechanical trauma on the dermis and its vasculature rather than any intrinsic properties of the tumor.³³⁶

In early lesions, there is often a small cyst with basophilic cells in the wall.³³⁷ Rarely, a pilomatricoma appears to arise in an established epidermal cyst³³⁸ or hair follicle.³³⁹ Pilomatricoma-like changes can also develop in the epidermal cysts in Gardner's syndrome (discussed previously). As the lesion ages, the number of basophilic cells decreases as the process of mummification outstrips the proliferation of the basophilic cells. Approximately 20% of lesions are fully keratinized (mummified) at the time of removal and have no basophilic cells remaining.^{329,337} Transepidermal elimination of the tumor is a rare outcome.^{340–346} In one case, perforation was present in the anetodermic variant.³⁰²

The immunohistochemical pattern indicates a tumor differentiating into both the hair cortex and the outer root sheath.³⁴⁷ The hard keratins hHa1, -a2, and -a5 are expressed in pilomatricomas but not in other tumors of follicular origin.^{348,349} Maturation to shadow cells is associated with a gradual loss of differentiation-specific hair keratins.³⁵⁰ CK15, found in trichoepitheliomas, some basal cell carcinomas, and proliferating trichilemmal cysts, *inter alia*, is not found in pilomatricomas.²⁴² The basaloid cells of all pilomatricomas express β -catenin, but the shadow cells do not stain.^{351–353} The transitional cells show strong staining for involucrin³⁴⁷ and bcl-2.³⁵⁴ The S100 proteins S100A2, S100A3, and S100A6, which specifically label certain cells within the normal hair follicle, are all expressed in different parts of a pilomatricoma.³⁵⁵

Pilomatrix dysplasia was the term used for a histologically distinctive pattern seen in a patient with facial dysmorphism and follicular papules who was receiving four immunosuppressive drugs.³⁵⁶ Hair follicles were dilated and contained hyperkeratotic and parakeratotic debris in place of hair shafts. There were hyperplastic areas of differentiation into hair matrix with cellular disorganization and loss of nuclear polarity.³⁵⁶ These changes are now known as trichodysplasia spinulosa (see p. 467). This description is left in this chapter in case readers unfamiliar with the entity read this section searching for clues to the diagnosis of a problem case.

Matricoma is the designation used by Ackerman and colleagues for a tumor with the same constituent cells as a pilomatricoma but with a different silhouette.¹³ The lesions are well circumscribed, not fundamentally cystic (although cystic areas can be present in some lobules), and composed of discrete aggregations. Some of these cases have probably been included with the 'proliferating pilomatricoma' (discussed previously).

Pilomatricomal horn is a verruca-like horn characterized by replacement of the epidermis by basaloid cells, with masses of cornified material containing shadow cells that form a cutaneous horn.³⁵⁷ This lesion is the matrical equivalent of the trichilemmal horn. Anetodermic changes, as seen in some cases of pilomatricoma, were present in the dermis in one case.³⁵⁷

Electron microscopy

The cells differentiate and keratinize in a manner analogous to the cells that form the cortex of the hair.³⁵⁸ The fully developed shadow cells

contain interlacing swirls of keratin that form a mantle around the nuclear remnants.³⁵⁸

Differential diagnosis

Examples of pilomatricoma that show predominantly basaloid cells can be confused with conventional basal cell carcinoma, but the latter tumor usually shows peripheral palisading and clefting artifact that separates tumor islands from adjacent fibromucinous matrix – features not seen in pilomatricoma. Basal cell carcinomas with pilar differentiation may rarely show matrical differentiation, but other more typical features of basal cell carcinoma can be found in microscopic sections. Pilomatricomas subjected to fine needle aspiration cytology can be confused with metastatic carcinoma; recognition of shadow cells in aspirates can then be a key to making the correct diagnosis.³⁵⁹ Shadow cells in general have been considered to be a clue to follicular differentiation; in addition to pilomatricoma and pilar basal cell carcinoma with matrical differentiation, they have been seen in hair shafts in some alopecias,²⁶⁹ the horn cysts of conventional and desmoplastic trichoepithelioma and microcystic adnexal carcinoma,^{269,360–362} mixed tumor of skin,²⁶⁹ proliferating trichilemmal tumor,³⁶¹ and even intracranial dermoid cyst.³⁶² Other features of these lesions should permit ready differentiation from pilomatricoma. As previously noted, changes of pilomatricoma can also be found in the epidermal cysts of Gardner's syndrome.

MELANOCYTIC MATRICOMA

Melanocytic matricoma was first reported in 1999 by Carlson *et al.*³⁶³ It recapitulates the bulb of the anagen hair follicle. The lesion presents as a small circumscribed papule, usually on the face.^{364,365} Resnik has challenged the validity of this entity, claiming it to be a morphological expression of matricoma.^{366,367} This has not been accepted by some.³⁶⁸

Examples of pilomatrix carcinomas with melanin pigment and intralesional melanocytes have been reported.^{369,370} Such cases can be regarded as the malignant counterpart of melanocytic matricoma (discussed previously), if indeed this is a discrete entity.³⁶⁹

Histopathology

Melanocytic matricoma is a well-circumscribed dermal nodule composed of variably melanized, pleomorphic, and mitotically active matrical and supramatrical cells with islands of shadow cells (Fig. 33.15).^{363,371} The shadow cells are not always plentiful. Admixed with these cells are numerous dendritic melanocytes containing melanin pigment. There has been no discernible connection with the overlying epidermis or a hair follicle. Pigmented matrical cells are sometimes seen in normal hair follicles (Fig. 33.16). An example of melanocytic matricoma has been described with expansile nests as well as single cells, dendritic and epithelioid cell types, and nuclear atypia with mitotic activity; the biologic significance of these changes is unclear, but similar examples of melanocytic colonization have been described in basal cell carcinomas and proliferative squamous lesions.³⁷²

The melanocytes express S100 protein and HMB-45, whereas the basaloid cells express β -catenin.³⁷³

Differential diagnosis

Tallon and Cerroni suggest that the features of melanocytic matricoma that distinguish it from pigmented pilomatricoma are the matrical and supramatrical proliferation of single or multiple nodules, predominantly in the dermis, the lack of a fundamental cystic structure, and the presence of only small clusters of shadow cells. They further suggest that pilomatricoma and matricoma could be ends of a spectrum, along with pigmented variants of each of these lesions.³⁷⁴

Figure 33.15 (A) Melanocytic matricoma. (B) Matrical cells and atypical melanocytic cells are present. (H&E)

TRICHOBLASTIC TUMORS

Trichoblastoma

Trichoblastomas are extremely rare benign tumors of the hair germ in which follicle development may be partly or completely recapitulated.^{76,163,375–377} They are constituted largely of follicular germinative cells.³⁷⁸ They have been likened to the odontogenic tumors, which may also be epithelial and/or mesenchymal.¹⁰ As initially reported by Headington, the trichogenic tumors were further classified on the basis of the relative proportions of epithelial and mesenchymal components: the predominantly epithelial trichogenic tumor was called a trichoblastoma, and the predominantly mesenchymal variant was labeled trichoblastic fibroma.³⁷⁹ Other categories include the trichoblastic myxoma, analogous to the odontogenic myxoma, and the rare trichogenic trichoblastoma, which displays advanced follicular differentiation.¹⁰ Other terms have also been used for tumors in this group, including solitary, giant and immature trichoepithelioma,^{163,380,381} and trichogerminoma.³⁸² The cutaneous lymphadenoma is a distinctive variant of trichoblastoma that is considered separately. The tumor reported as a ‘rippled-pattern trichomatricoma’ is also a trichoblastoma.³⁸³

Figure 33.16 Pigmented matrical cells in a normal hair follicle. (H&E)

Trichoblastomas are usually greater than 1 cm in diameter and involve the deep dermis and subcutis. Lesions confined to the subcutis are seen occasionally.³⁸⁴ They usually present as a slowly growing nodule. A case with a keratin-filled dilated pore in the center of the lesion has been reported.³⁸⁵ The head, particularly the scalp, is a common site.³⁸⁶ The eyelid is a rare site.³⁸⁷ Multiple lesions have been reported.³⁸⁸ Trichoblastoma and syringocystadenoma papilliferum are two common tumors that arise in organoid nevi.³⁸⁹ Trichoblastoma changes have been found to extend radially from the walls of infundibular cysts.³⁹⁰ Trichoblastomas are not aggressive unless they have been misdiagnosed or contain an element of basal cell carcinoma.^{13,391} There have been combinations of trichoblastomas with melanocytic nevi.³⁹² Merkel cell carcinoma has arisen within a cystic trichoblastoma, suggesting a histogenetic link between follicular Merkel cells and Merkel cell carcinoma.³⁹³ There is a rare report of melanoma arising in a long-standing pigmented trichoblastoma. The lesion had a rare NRAS mutation (c.34G>T (G12C)) and led to widespread metastasis and death of the patient.³⁹⁴

Whereas basal cell carcinomas and trichoepitheliomas are characterized by mutations in the *PTCH* gene, such mutations are not common in sporadic trichoblastomas.³⁹⁵ The genetic basis of trichoblastomas remains elusive.³⁹⁵

Histopathology^{10,376}

The low-power view is usually quite striking: a large, circumscribed basaloid tumor with no epidermal connection. It is usually situated in the mid and lower dermis, with extension into the subcutis. The tumor shows irregular nests of basaloid cells resembling a basal cell carcinoma but with variable stromal condensation and pilar differentiation (Fig. 33.17). The variant reported as **trichogerminoma** was composed of closely packed lobules of basaloid cells resembling hair bulbs, with little intervening stroma.^{382,396} It has also been regarded as a variant of (large nodular) trichoblastoma with less overt follicular differentiation (Fig. 33.18).²¹⁴ Foci of necrosis may be present in this variant.³⁹⁶ At the other end of the spectrum is the *trichoblastic fibroma*, with an intimate relationship between basaloid nests and strands, and a fibrocellular stroma.^{397–399} A desmoplastic stroma has been reported (Fig. 33.19).⁴⁰⁰ So-called ‘stromal induction’, with the formation of primitive hair bulbs, is present. Keratinous cysts may be present in this group of trichoblastomas, but they are not seen in the cellular, basaloid variants that may resemble basal cell carcinoma. In the so-called trichoblastic infundibular cyst, reticulated cords of epithelial cells extend outward from the cyst wall; these can include matrical cells and a surrounding dense cellular stroma.³⁹⁰

Figure 33.17 Trichoblastoma. This basaloid tumor resembles basal cell carcinoma. There is some trichogenic differentiation and stromal induction. (H&E)

Figure 33.18 Trichogerminoma. There are closely packed lobules of basaloid cells. The cellular 'balls' within the tumor islands give a vague suggestion of hair bulb formation. (H&E)

Figure 33.19 Trichoblastic fibroma. There are interconnecting cords of basaloid cells, forming an intimate relationship with a fibrocellular stroma. (H&E)

Figure 33.20 Pigmented trichoblastoma. There is focal stromal induction with the formation of primitive follicular structures. (H&E)

Ackerman and colleagues have used 'trichoblastoma' as a generic term for all neoplasms of the skin and subcutaneous fat that are composed mostly of follicular germinative cells. Trichoepitheliomas are included in this definition.¹³ They have reported nodular, retiform, cribriform, racemiform, and columnar patterns of trichoblastoma.¹³

Stromal amyloid and Merkel cells are quite common in trichoblastomas.^{163,214,401} Rare variants include clear cell,⁴⁰² pigmented (pigmented trichoblastoma),^{403,404} adamantinoid (Fig. 33.20),³⁷⁸ and granular trichoblastomas.⁴⁰⁵ A variant of pigmented trichoblastoma colonized by abundant dendritic melanocytes has been called a **melanotrichoblastoma**.⁴⁰⁶ Focal sebaceous and apocrine differentiation are rare.^{407–409} It is generally agreed that the cutaneous lymphadenoma is an adamantinoid variant of trichoblastoma with lymphocytic infiltration of the basaloid nests (see later). Trichoblastomas with basal cell carcinoma-like foci have been reported. Such tumors do not express CK15 as do other trichoblastomas. Furthermore, they lose their Merkel cells.⁴¹⁰ A trichoblastoma arising within an apocrine poroma, which also showed sebaceous differentiation, has been reported.⁴¹¹ The cells in a

trichoblastoma express CK8 and CK19.⁴¹² CK7 is often expressed, in contrast to trichoepithelioma.²⁴⁰ Both trichoblastomas and trichoepitheliomas are characterized by papillary mesenchymal bodies that express CD10.²¹⁴ Trichoblastomas and trichoepitheliomas do not express androgen receptors; they are expressed in basal cell carcinomas.⁴¹³ Neither trichoblastomas nor basal cell carcinomas express hair keratins.⁴¹⁴ Nestin, an intermediate filament protein implicated in epithelial–stromal interactions of developing anagen follicles, is positive in stromal cells of trichoblastomas and negative in basal cell carcinomas.⁴¹⁵ In the study by Battistella *et al.*, clear cell and granular cell trichoblastomas were diffusely positive for the follicular stem cell marker PHLDA1, whereas comparable types of basal cell carcinoma were negative.⁴⁰⁵

The *rippled-pattern trichoblastoma* has a palisaded arrangement of epithelial ribbons with areas of nuclear palisading resembling Verocay bodies. Focal sebaceous differentiation may occur. The expression of cytokeratins is similar to the more usual trichoblastoma.⁴¹⁶ The trichoblastic myxoma features a cellular, mucinous stroma, whereas the

trichogenic trichoblastoma displays a centrifugal organization of the tumor, in which hair bulbs are arranged at the periphery of tumor islands and hairs are arranged centrally, found within small keratinizing cysts.⁴¹⁷

Differential diagnosis

The cellular ‘balls’ in trichoblastoma (trichogerminoma) represent a distinctive feature distinguishing this tumor from basal cell carcinoma or trichoepithelioma. Separation of trichoblastic fibroma from basaloid follicular hamartoma can be challenging because the latter also shows single-file cords of cells and a close association of epithelium and stroma. However, embryonic hair follicle-like structures are not as commonly seen in basaloid follicular hamartoma as they are in trichoblastoma. Trichogenic trichoblastomas that produce hair could have some features in common with trichofolliculomas, but the former are larger tumors that are less differentiated and do not show the organization of small but mature secondary follicles entering on a central, cystically dilated follicle. Some have suggested that trichoblastic tumors are simply variants of trichoepithelioma. However, the former often appear quite different clinically (larger lesions, often in locations other than the head and neck) and have much more variable histopathology with, in some cases, more advanced follicular differentiation. In several immunohistochemical studies of small nodular and rippled-pattern trichoblastomas, Yamamoto and associates found similar keratin profiles in the two trichoblastic tumors, including expression of CK7, which is not found in trichoepithelioma.^{240,416} CD10 may be of some use in separating basal cell carcinoma from trichoblastoma; trichoblastomas show only peritumoral stromal staining for CD10, whereas basal cell carcinomas typically show intraepithelial staining. A combination of both epithelial and peritumoral stromal staining is seen in basal cell carcinomas with follicular differentiation.⁴¹⁸ As noted previously, staining for nestin could be exploited in differential diagnosis because (in contrast to trichoblastomas) peritumoral stroma is negative in basal cell carcinomas.⁴¹⁵ There is also a difference in laminin 5, γ_2 chain expression between the two tumors. This basement membrane constituent is expressed at the invasive front of many tumors, including basal cell carcinomas (in which staining is diffusely positive), whereas most trichoblastomas are negative, with the few positive cases showing staining only at the tumor periphery of branching cellular cords.⁴¹⁹

Cutaneous lymphadenoma (trichoblastoma variant)

Cutaneous lymphadenoma is a rare adnexal tumor with a prominent lymphocytic infiltrate in the tumor nests.^{420–428} It is a distinctive variant of trichoblastoma.⁴²¹ It has also been called ‘lymphotropic adamantinoid trichoblastoma’.⁴²⁹ The tumor presents as a small nodule on the face, legs, or back.⁴³⁰ The lesion has usually been present for many months or years. Most cases develop in adults; onset in adolescence is rare.^{429,431,432,434}

Local excision is curative.

Histopathology

Cutaneous lymphadenoma is composed of multiple rounded lobules of basaloid cells with some degree of peripheral palisading, embedded in a fibrous stroma of variable density (Fig. 33.21). The stroma may rarely be desmoplastic.⁴³² There is an intense infiltrate of small mature lymphocytes within the lobules, with some spillage into the stroma.⁴²⁴ A hint of follicular differentiation and focal sebaceous differentiation is sometimes present.⁴²⁵ Some nests may show adamantinoid features, but this does not appear to be a universal change – a strong point against cutaneous lymphadenoma being synonymous with adamantinoid trichoblastoma.⁴³³ Focal stromal mucinosis is an uncommon finding.⁴²⁷

Figure 33.21 (A) Cutaneous lymphadenoma. (B) Lymphocytes extend into the basaloid nests. (H&E)

Both T and B lymphocytes are found within the lobules, as well as some S100-positive dendritic cells.^{422,431} The pattern of staining with CD34 and bcl-2 is similar to that seen in trichoblastomas and trichoepitheliomas.⁴³⁴ There are scattered CD30⁺ cells within the tumor nests.^{434–436} Focal staining with CD15 has also been reported.⁴³⁶ Another study found a predominance of memory T cells and an infiltrate of Foxp3⁺ Treg cells.⁴³⁷ The epithelial cells are usually positive for cytokeratin and EMA.⁴³⁸

Panfolliculoma

Panfolliculoma is an exceedingly rare but distinctive tumor with advanced follicular differentiation. It was described by Ackerman and colleagues.¹³ It has overlap features between a trichoblastoma (discussed previously) and a matricoma (see p. 916), but it differs from the former by the presence of differentiation toward all elements of the follicle, including cystic structures containing corneocytes. Matrical differentiation is less conspicuous than it is in matricoma. A cystic variant has been described (Fig. 33.22),⁴³⁹ and there have been several reports of panfolliculoma confined to the epidermis.^{440,441} An example with sebaceous differentiation has been described; it featured clusters of EMA-positive sebocytes near infundibulocystic elements or among follicular germinative cells.⁴⁴²

Figure 33.22 Cystic panfolliculoma. Follicular differentiation is present in the basaloid nests. There is no matrical differentiation in this field. (H&E)

NEOPLASMS WITH DIFFERENTIATION TOWARD FOLLICULAR MESENCHYME

The two tumors in this category are characterized by a prominent component of perifollicular mesenchyme, but follicular elements are also present. The fibrofolliculoma and trichodiscoma, previously regarded as separate tumors, are considered together, for the reasons listed here. The second tumor in this category, the neurofollicular hamartoma, has many features in common with the folliculosebaceous cystic hamartoma, regarded as an end-stage variant of trichofolliculoma, but the presence of a unique mesenchymal component justifies its continued existence as a discrete entity.

The *perifollicular fibroma* is a controversial entity of doubtful existence. This term has been used for angiofibromas^{443,444} and fibrofolliculomas.^{445,446} It should no longer be used. A relatively recently reported perifolliculoma-like lesion was thought to have resulted from trauma.⁴⁴⁷

FIBROFOLLICULOMA/TRICHODISCOMA

Although fibrofolliculomas and trichodiscomas are quite different at first glance, Ackerman and colleagues presented evidence that they are different stages in the development of a single entity.¹³ For this reason, the composite designation fibrofolliculoma/trichodiscoma is used here.

Both variants are found as asymptomatic skin-colored papules 1–3 mm in diameter, usually on the face. Other sites include the arms, trunk, and thighs. A hair follicle may be present within the lesion. The lesions may be solitary or multiple with up to several hundred lesions present. Most cases develop in the third decade of life and persist thereafter.¹³ A linear and a congenital annular variant have been described.^{448,449} Multiple lesions may be found in pure form,^{450,451} or they may be associated with the Birt–Hogg–Dubé syndrome (see later).^{452–459} Fibrofolliculomas have also been associated with nevus lipomatosus. The lesions were present at birth.⁴⁶⁰

The origin of these tumors is uncertain. Ackerman and colleagues regard these tumors as hamartomas, but not one related to the hair disk (Haarscheibe), as was originally proposed for trichodiscoma.¹³ The hair disk, a specialized component of the perifollicular mesenchyme,

Figure 33.23 Perifollicular fibroma (fibrofolliculoma). Lamellar fibrosis surrounds two cross-sectional profiles of hair follicles. One of these shows small branching epithelial cords – a characteristic feature of fibrofolliculoma and evidence that perifollicular fibroma is actually a form of fibrofolliculoma. (H&E)

is a richly vascular dermal pad that serves as a slowly adapting mechanoreceptor.^{450,461,462}

Birt–Hogg–Dubé syndrome

The Birt–Hogg–Dubé syndrome (OMIM 135150) is an autosomal dominant genodermatosis characterized by cutaneous fibrofolliculomas⁴⁶³ and an increased risk of multiple lung cysts,⁴⁶⁴ spontaneous pneumothorax,⁴⁶⁵ and renal tumors.^{466,467} The renal tumors include hybrid oncocytic neoplasms and chromophobe renal cell carcinomas.^{468–470} Colonic polyps, neural tumors, and oncocytic parotid tumors have also been reported in this syndrome.^{470–473} The syndrome is caused by mutations in the *FLCN* (*BHD*) gene on chromosome 17p11.2, which encodes the protein folliculin. Several different mutations in this gene, which has a tumor suppressor role, have been reported.⁴⁷⁴ Initially, it was thought that the syndrome was characterized by three distinct cutaneous tumors – fibrofolliculomas, trichodiscomas, and acrochordons – but these three lesions are now all regarded as being fibrofolliculomas.⁴⁷⁵ As a consequence, the existence of this syndrome was, for a period, called into question.⁴⁷⁶ Likewise, the perifollicular fibroma is also a fibrofolliculoma (Fig. 33.23). Accordingly, it seems that some or all of the patients with the Hornstein–Knickenberg syndrome, in which ‘perifollicular fibromas’ are a feature, actually have the Birt–Hogg–Dubé syndrome.^{475,477,478}

Histopathology

It is now accepted that the fibrofolliculomas and trichodiscomas of the Birt–Hogg–Dubé syndrome are the same entity (fibrofolliculoma) but with a spectrum of morphological changes. It is inferred, but not proven, that sporadic cases may have either of these two morphologies. Furthermore, some cases reported as trichodiscomas have illustrations showing fibrofolliculomas.⁴⁷⁹

The *fibrofolliculoma* end of the spectrum consists of cords and strands of epithelial cells, two to four cells thick, radiating from a follicular structure with infundibular features. This may be dilated and contain keratin. The strands may anastomose or rejoin the infundibulum at several points (Fig. 33.24). One or more sebocytes may be seen within the epithelial cords. They may form tiny lobules. Sebaceous ducts may also be present. The term ‘mantleoma’ has also been used

Figure 33.24 Fibrofolliculoma. The centrally located follicular unit is distorted, with branching cords of epithelium that penetrate the surrounding connective tissue. (H&E)

Figure 33.25 Trichodiscoma. A poorly defined angiofibroma-like proliferation is present in the upper dermis. (H&E)

for these tumors. Around the epithelial cords, there is a well-circumscribed proliferation of loose connective tissue composed of fine fibers with some intervening mucin. Elastic fibers are scant or absent.

The *trichodiscoma* component is usually a well-demarcated and non-encapsulated tumor, which often has a folliculosebaceous collar-ette of variable maturity. Areas resembling fibrofolliculoma may be seen, particularly at the periphery. Trichodiscomas are composed of fascicles of loose, finely fibrillar connective tissue with intervening mucinous ground substance (Fig. 33.25). There is a moderate increase in fibroblasts, with occasional stellate forms. Elastic fibers are sparse or absent. There are prominent small vessels, some of which are telangiectatic. Sometimes, blood vessels with a concentric arrangement of PAS-positive collagen, forming a thickened wall, have been present toward the lower edge of the tumor. The term ‘perivascular fibroma’ has been used for these changes.⁴⁸⁰ Nerve fibers have been described at the periphery of the lesions and also extending into the base. Neu-

rofollicular hamartoma (see later) is now regarded as a spindle cell-predominant trichodiscoma.⁴⁸¹

Both syndromic-associated and sporadic types of fibrofolliculomas and trichodiscomas have identical immunophenotypic features with perfollicular vimentin and CD34 but not factor XIIIa.^{482–485} Spindle cell-predominant trichodiscomas also occur; these have overlapping features with neurofollicular hamartoma (see later), but the cells at least partly express CD34 and are S100 negative. Variant forms feature palisading of stromal elements, mimicking schwannoma,⁴⁸⁶ lipomatous metaplasia,⁴⁸⁷ or pleomorphic stromal cells suggesting ancient change (‘symplastic trichodiscoma’).^{487,488}

Multiple giant tumors with the appearances of a trichodiscoma have been reported as ‘**giant fibromyxoid tumors of the adventitial dermis**’.

Electron microscopy

Trichodiscomas have shown deposits of fibrillar-amorphous material between the collagen bundles.⁴⁶¹ The significance of this material is uncertain. Banded structures and a Merkel cell–neurite complex in the basal layer of the epidermis have also been noted, although Merkel cells are not seen in the dermis.⁴⁶¹

NEUROFOLLICULAR HAMARTOMA

The neurofollicular hamartoma is a rare tumor found on the face, usually near the nose. It presents as a pale papule, usually solitary, that measures 3–7 mm in diameter.^{489–492} Kutzner and colleagues proposed that the neurofollicular hamartoma (or at least S100-negative variants of it) should be recategorized as a spindle cell-predominant trichodiscoma.⁴⁸¹

Histopathology

The lesion consists of hyperplastic pilosebaceous units with an intervening stroma of spindle cells arranged in broad, haphazard fascicles. The stroma has features of both an angiofibroma and a neurofibroma. It also resembles a trichodiscoma.

It has been suggested that the neurofollicular hamartoma, trichodiscoma, and fibrofolliculoma are part of the same spectrum of hamartomas⁴⁸⁹ and, as stated previously, that the neurofollicular hamartoma should be recategorized as a spindle cell-predominant trichodiscoma. The folliculosebaceous cystic hamartoma is closely related (see p. 924).⁴⁹³

The spindle cell-predominant trichodiscoma and the usual trichodiscoma express an identical CD13⁺/CD34⁺ fibrocytic immunophenotype without coexpression of neural/perineural, myogenic, or melanocytic markers.⁴⁸⁴ It is composed of cellular fascicles of spindle cells set in a loosely textured stroma with a moderate mucinous background.⁴⁸¹

Immunohistochemistry of the neurofollicular hamartoma shows scattered cells that are positive for S100 and factor XIIIa. Diffuse staining for S100 has also been reported.⁴⁹² Most of the connective tissue cells are positive for vimentin.⁴⁸⁹

MALIGNANT PILAR NEOPLASMS

TRICHILEMMAL CARCINOMA

Headington defined trichilemmal carcinoma (trichilemmocarcinoma)⁴⁹⁴ as a ‘histologically invasive, cytologically atypical clear cell neoplasm of adnexal keratinocytes which is in continuity with the epidermis and/or follicular epithelium’.^{10,495} Only a small number of cases purporting to be this entity have been reported.^{10,494,496–502} The illustrations in some of the reported cases resemble invasive intraepidermal carcinoma, a tumor that often shows adnexal differentiation in

its dermal component.^{494,503} Ackerman believed that true trichilemmal carcinoma is a rare expression of basal cell carcinoma (trichoblastic carcinoma) and that what 'conventionally is called trichilemmal carcinoma is a clear cell variant of squamous cell carcinoma';⁵⁰⁴ on this basis, the existence of trichilemmal carcinoma has been questioned (see p. 818). The editor is sympathetic to this viewpoint. Another aspect of this controversy was discussed by Misago, who proposed that infundibular squamous cell carcinoma is a distinct entity (with a possible link to keratoacanthoma) and that true 'trichilemmal carcinoma' is a rare occurrence, one type of which may be related to the infundibular squamous cell carcinoma.⁵⁰⁵

The tumors reported as trichilemmal carcinoma have usually arisen in the sun-exposed skin of the face and extremities of elderly patients.⁵⁰⁶ They are usually diagnosed clinically as a basal cell carcinoma. Their development in Cowden's disease is surprisingly rare.⁵⁰⁷ A case has been reported in an organoid nevus, in continuity with a trichoblastoma that was also in the nevus.⁵⁰⁸ The hypercalcemia of malignancy was present in one extensive lesion that arose in a burn scar.⁵⁰⁹

Treatment is by wide surgical excision.

Histopathology

The tumors are multilobulate, infiltrative growths connected to the epidermis and pilosebaceous structures and showing features reminiscent of the outer root sheath.⁴⁹⁸ The lobules often show peripheral palisading, hyaline basement membranes, and trichilemmal keratinization (Fig. 33.26).⁴⁹⁸ A high mitotic rate is often present.^{497,499} Neuroendocrine differentiation and melanocyte colonization were present in one case. This tumor expressed EMA, CK15/20, chromogranin, synaptophysin, and CD56.⁵¹⁰ The usual trichilemmal carcinoma expresses CK7⁵⁰⁸ and podoplanin, which is detected by the D2-40 antibody.⁵¹¹

The tumor reported as 'clear cell pilar sheath tumor of scalp' had some histological similarities to the trichilemmal carcinoma. The reported case was composed of small nests of glycogen-containing clear cells infiltrating the dermis and subcutis.⁵¹² There was no underlying cyst or evidence of trichilemmal keratinization.⁵¹²

PILOMATRIX CARCINOMA

More than 50 cases of pilomatrix carcinoma (matrical carcinoma) have now been reported.⁵¹³⁻⁵²⁴ It usually arises, *de novo*, as a solitary lesion, but some cases arise in a pilomatrixoma or at the site of a previously

Figure 33.26 Trichilemmal carcinoma. This tumor is focally infiltrative. Some clear cells are present near the base of the tumor. (H&E)

excised pilomatrixoma.⁵²⁵ In one case, the patient had multiple pilomatrixomas.⁵²⁶ Although they are most common in the elderly, cases in young adults and even children have been reported.⁵²⁷ There is a male predominance. Lesions are usually situated on the scalp and face, but they have been reported on most body sites.^{528,529} They may measure from 0.6 to 10 cm in diameter.

Mutations in the *CTNNB1* gene, which encodes β -catenin, have been reported in most cases of pilomatrix carcinoma.⁵³⁰ Similar mutations are found in benign pilomatrixomas. Neither molecular nor immunohistochemical methods distinguish pilomatrix carcinomas from pilomatrixomas. Their distinction remains a histological one.⁵³⁰

Pilomatrix carcinomas have a high capacity for local infiltration; local recurrences are common. Metastases are infrequent. It can spread to regional lymph nodes⁵³¹ and to visceral organs, particularly the lungs.⁵²⁸ A **pilomatrical carcinosarcoma** of the cheek with pulmonary metastases has been reported.²⁶⁸ The author has seen a further case, in consultation.

Treatment is by wide local excision. Follow-up is necessary because local recurrence and metastases may be delayed.⁵³² Radiation therapy has been used for recurrences and nodal metastases, but its role in treatment is unclear.⁵²⁸

Histopathology

Pilomatrix carcinoma is a poorly circumscribed, asymmetrical tumor that is often ulcerated.⁵²⁹ It is centered on the dermis, but extension into the subcutaneous tissue often occurs. The tumor is composed of pleomorphic basaloid cells with prominent nucleoli and frequent mitoses. Necrosis is sometimes present. Keratotic material and shadow cells may be present in the center of the basaloid islands (Fig. 33.27). Vascular and/or lymphatic invasion are rare.^{513,517}

Melanin pigment and intralesional melanocytes have been present in several cases.^{369,370} Such cases can be regarded as the malignant counterpart of the melanocytic matricoma (see later).³⁶⁹ The case reported as a pilomatrical carcinosarcoma was composed of a large pilomatrixoma lying within a spindled, sarcomatoid stroma.²⁶⁸

It should be remembered that shadow cell differentiation can occur in some visceral tumors, such as tumors of the colon and uterus.⁵³³ They have also been observed in a cutaneous metastasis of ovarian carcinoma.⁵³⁴

Figure 33.27 Pilomatrix carcinoma. There are pleomorphic basaloid cells and keratotic material with some shadow cell formation. (H&E)

Immunohistochemical studies have demonstrated the hair matrix and precortex keratins hHa5 and hHa1.⁵³⁵ β -Catenin is also expressed, as in pilomatrixomas.⁵³⁵⁻⁵³⁷

Differential diagnosis

Pilomatrix carcinomas should be distinguished from proliferating pilomatricoma and aggressive pilomatricoma. **Proliferating pilomatricomas** feature mostly basaloid cells with scant cytoplasm, hyperchromatic nuclei, and mitotic activity. However, these are symmetrical, well-circumscribed lesions that demonstrate expansile growth.⁵³⁸ **Aggressive pilomatricomas** have an infiltrative growth pattern and display mild cytologic atypia, although they are mitotically active.⁵³⁸ This type of 'intermediate' lesion, which some might regard as a 'low-grade malignancy', can be found among other categories of adnexal tumors, examples being acrospiromas and poromas. β -Catenin, a protein involved in signal transduction, is recognized as an oncogene in colon cancer and melanoma. Several recent studies have investigated the expression of β -catenin in the basaloid cells of pilomatricoma because its expression has been found to correlate with mutations in its encoding gene *CTNNB1*. However, both pilomatricomas and pilomatrix carcinomas show nuclear and cytoplasmic expression of β -catenin, indicating that (1) its expression does not explain the differences in biologic behavior of these two tumors, and (2) staining for β -catenin cannot be exploited in differentiating between pilomatricoma and pilomatrix carcinoma. However, the findings lend support to the idea that pilomatrix carcinomas occasionally may indeed arise from preexisting pilomatricomas. Currently, these two tumors are generally distinguished by a combination of clinical history and the 'malignant features' (nuclear pleomorphism, prominent nucleoli, frequent mitoses, necrosis, and overall growth pattern) in pilomatrix carcinoma. Small samples of pilomatrix carcinomas may create confusion with lymphoepithelioma-like carcinoma⁵³⁹ or undifferentiated metastatic carcinoma.

TRICHOBLASTIC CARCINOMA/SARCOMA/ CARCINOSARCOMA

These three variants of malignant trichoblastoma are considered together because of their extreme rarity. The *trichoblastic carcinoma* (malignant trichoblastoma) is a high-grade carcinoma arising in a trichoblastoma. Two of the four cases reported up to 2005 had died with metastatic disease.^{382,540} One of the trichoblastic carcinomas arose in the base of a trichoepithelioma in an elderly female with the Brooke-Spiegler syndrome.⁵⁴¹ Another reported case was also associated with multiple familial trichoepitheliomas.⁵⁴² Low-grade trichoblastic carcinomas are synonymous with basal cell carcinomas in some classifications.¹³ All cases of trichoblastic carcinoma have been characterized by an undifferentiated carcinoma with numerous mitoses and some necrosis. Basaloid and spindle cell areas are sometimes present.⁵⁴¹

The term *trichoblastic sarcoma* has been applied to a high-grade stromal tumor arising in a trichoblastoma.⁵⁴³ The lesion, which was located on the posterior neck, had been present for many years, but there had been rapid growth in the months preceding its removal. The tumor consisted of a multifocal proliferation of basaloid follicular cells with a retiform growth pattern surrounded by a stroma resembling the perifollicular sheath.⁵⁴³ In places, the stroma showed abrupt transition into a pleomorphic proliferation of large sarcomatous cells with frequent and often atypical mitoses.⁵⁴³ The stromal cells expressed CD10, whereas the basaloid cells were positive for cytokeratins and 34 β E12.⁵⁴³

Both a high-grade and a low-grade *trichoblastic carcinosarcoma* of the skin have been reported.^{544,545} The authors believed that the two cases were authentic carcinosarcomas and not examples of metaplastic carcinoma.⁵⁴⁵ Both tumors were composed of two discrete

components: the first was epithelial with some basaloid cells with frequent mitotic figures, nuclear atypia, and focal nuclear crowding; the second was a stromal component that was composed of pleomorphic spindle-shaped cells with some bizarre multinucleated cells in this high-grade lesion.^{544,545} The epithelial cell component stained for cytokeratin (AE1/AE3) and the stromal component for vimentin but not cytokeratin.⁵⁴⁵ There was no recurrence of either tumor at follow-up. Further cases have since been reported. An underlying B-cell chronic lymphocytic leukemia was present in one case of trichoblastic carcinosarcoma and also in a trichogenic carcinoma in the same series.⁵⁴⁶

There has been a recent report of two cases of a panfollicular tumor showing features of malignancy and variations of matrical, inner and outer root sheath, and sebaceous differentiation. Immunohistochemical stains were focally positive for PHLDA-1 (follicular stem cells), β -catenin (basaloid cells of pilomatricoma and pilomatrix carcinoma), and BerEP4 (suggesting germinative differentiation).⁵⁴⁷

SEBACEOUS TUMORS

Sebaceous tumors are relatively uncommon tumors of the skin. They are derived from the sebaceous gland, which begins its development as a bulge or collar at the junction of the infundibulum and isthmus of the hair follicle. The sebaceous gland may be derived from CK15⁺ stem cells located in the hair follicle bulge.⁵⁴⁸ Early in life, small cords of basaloid cells extend downward on either side of the follicle, forming the so-called 'mantle'. Maturation of the mantle occurs slowly in childhood with the accumulation of lipid in some of the cells, forming sebocytes at the base of the mantle. Sebocytes increase in number and size such that a fully developed sebaceous lobule is present by puberty. Mantles are best seen around vellus follicles on the face, but they also develop in association with terminal follicles. Later in life, the sebaceous glands undergo progressive involution so that mantles are again seen, this time as vestiges. Initially, Steffen and Ackerman suggested that sebaceous glands had several cycles of growth, involution, and rest, independent of the cycle of the hair follicle.⁵⁴⁹ Ackerman has since modified this view by suggesting that the cycle occurs 'but twice in a lifetime (involution early in infancy, evolution at puberty, and involution again at menopause)'.⁵⁵⁰ The latest theory may not be absolute because one occasionally sees a mantle in mid-adult life.

The synthesis and accumulation of lipids is a key step in the differentiation of sebaceous gland cells.⁵⁵¹ Proteins involved in adipocyte differentiation, such as galectin-12, resistin, SREBP-1, and stearyl-CoA desaturase (SCD), have also been detected in sebaceous glands of human scalp skin.⁵⁵¹ The periphery of normal sebaceous glands contains podoplanin, a sialoglycoprotein found also in lymphatics and identified by the D2-40 monoclonal antibody.⁵⁵²

The following categories of sebaceous tumors are considered:

- Ectopic sebaceous glands
- Hamartomas and hyperplasias of sebaceous glands
- Benign sebaceous tumors
- Malignant sebaceous tumors
- Tumors with focal sebaceous differentiation.

ECTOPIC SEBACEOUS GLANDS

FORDYCE'S SPOTS AND RELATED ECTOPIAS

Sebaceous glands are usually found in association with hair follicles, the so-called 'pilosebaceous unit'. Ectopic sebaceous glands without attached follicles (Fig. 33.28) may be found as tiny yellow papules near mucocutaneous junctions, particularly the upper lip, and in the buccal

Figure 33.28 Montgomery's tubercle. An ectopic sebaceous gland opens directly onto the surface. (H&E)

mucosa (*Fordyce's spots*).²⁷⁰ They may also be found in the areolae of the breasts, where they are known as *Montgomery's tubercles*. They are said to be restricted to the female breast, but the author has seen a case from a male breast. Like Fordyce's spots, the sebaceous gland in a Montgomery's tubercle opens directly onto the surface.

Ectopic sebaceous glands can also be found on the penis (Tyson's gland),^{553,554} labia minora, and, very rarely, in the esophagus and vagina.⁵⁵⁵ An ectopic sebaceous gland has been reported within the hair matrix epithelium of an anagen hair follicle on the chin.⁵⁵⁶

PSEUDONEOPLASTIC SEBACEOUS PROLIFERATIONS

By far the most common abnormality of the sebaceous gland is sebaceous hyperplasia. The hamartomas are quite uncommon and include folliculosebaceous cystic hamartoma and steatocystoma. Organoid nevus (nevus sebaceus) involves other appendageal components and is considered with the complex adnexal tumors (see p. 951).

SEBACEOUS HYPERPLASIA

Sebaceous hyperplasia occurs as asymptomatic, solitary or multiple yellowish papules, often umbilicated, on the forehead and cheeks of elderly and sometimes younger individuals.⁵⁵⁷⁻⁵⁶¹ An infant with congenital papules and plaques on the face has been reported.⁵⁶² It has been suggested that such examples of 'premature' sebaceous hyperplasia may instead represent a form of sebaceous hamartoma.⁵⁶³ Clinically, sebaceous hyperplasia may mimic basal cell carcinoma. Rare variants include a 'giant' form,^{564,565} a linear or zosteriform arrangement,^{566,567} a plaque composed of multiple papules,⁵⁶⁸ a diffuse form,⁵⁶⁹ a familial occurrence,^{570,571} and involvement of the areola,⁵⁷²⁻⁵⁷⁵ penis,⁵⁶⁷ scrotum,⁵⁷⁶ or vulva.⁵⁷⁷⁻⁵⁷⁹ Sebaceous hyperplasia is seen in heart transplant recipients. It is thought to be related to the process of dysplastic epithelial proliferation in transplant recipients and not to the effects of cyclosporine (ciclosporin),⁵⁸⁰ although this has been disputed.⁵⁸¹ Sebaceous hyperplasia was present in 30% of renal transplant recipients in one series.⁵⁸² These patients had a higher incidence of non-melanoma skin cancer than transplant recipients without sebaceous hyperplasia. It has also been seen in a bone marrow recipient; cyclosporine was implicated in this case.⁵⁸³ Highly active antiretroviral therapy (HAART) has been implicated in the causation of sebaceous gland hyperplasia in a patient with HIV infection.⁵⁸⁴

Figure 33.29 Sebaceous gland hyperplasia. Lobules of enlarged, mature sebaceous glands are attached to a central hair follicle. (H&E)

Juxtaclavicular beaded lines – tiny papules arranged in closely placed parallel rows, resembling 'strands of beads' – are a variant of sebaceous gland hyperplasia.⁵⁸⁵⁻⁵⁸⁷ They are asymptomatic and skin-colored to slightly yellow. They are said to be arranged along skin tension lines in the supra- and subclavicular area; they may be seen at other sites, such as the face⁵⁸⁸ and penis.⁵⁸⁹ The condition is said to be more common in dark-skinned people.⁵⁹⁰

The etiopathogenesis of sebaceous hyperplasia is unknown. Interestingly, sebaceous hyperplasia can be produced in rats by the topical application of citral (3,7-dimethyl-2,6-octadienal), a chemical used in foods as a flavoring agent.⁵⁹¹

The dermoscopic features of sebaceous hyperplasia consist of the 'cumulus sign' (because of the resemblance to cumulus clouds) and the 'bonbon toffee sign', in which the cumulus sign surrounds a central umbilication.⁵⁹²

Histopathology

Large, mature sebaceous lobules are grouped around a central dilated duct, which is usually filled with debris, bacteria, and, occasionally, a vellus hair. The lobules usually lack the indentations by fibrous septa that characterize the normal gland (**Fig. 33.29**). The sebocytes are smaller than usual, and there are more basal cells per unit basement membrane length than in normal glands. Autoradiographic studies have shown a lower labeling index.⁵⁹³ Sebaceous hyperplasia may be a clue to an underlying dermatofibroma. In shallow shave biopsies, sebaceous glands may be the most conspicuous feature.⁵⁹⁴

In juxtaclavicular beaded lines, there may be isolated sebaceous lobules in the upper dermis, not obviously connected with hair follicles.⁵⁸⁵

Although sebaceous glands are prominent in rhinophyma, the sebaceous lobules are not as well-defined and grouped as in sebaceous hyperplasia.

STEATOCYSTOMA

The steatocystoma is a cystic structure lined by epithelium resembling the sebaceous duct (**Fig. 33.30**). Sebaceous lobules and individual sebaceous cells are present within the lining epithelium. Steatocystoma has been considered in detail with other cysts (see p. 517).

FOLLICULOSEBACEOUS CYSTIC HAMARTOMA

The folliculosebaceous cystic hamartoma is a distinctive hamartoma composed of folliculosebaceous structures surrounded by a stroma

Figure 33.30 Steatocystoma. There are mature sebaceous glands in the wall of a cyst. (H&E)

consisting of various mesenchymal components.^{493,595–598} It presents as a solitary papule or nodule 0.5–2 cm or more in diameter, usually on the face.⁵⁹⁹ Other rare sites of involvement include the scalp,^{600,601} upper arm,⁶⁰² nipple, and genital region.⁶⁰³ A giant variant, replacing the scrotum, has been reported.⁶⁰⁴ Another giant lesion was of congenital origin.⁶⁰⁵ In one case, the lesion arose in a port-wine stain.⁶⁰⁶ Lesions are usually removed in adulthood, although they have often been present for many years. Schulz and Hartschuh presented convincing evidence that this lesion is a trichofolliculoma at its very late stage with the follicular structures in a state of involution, corresponding to the normal hair cycle.¹⁵⁸ Others agree with this concept but suggest the designation sebofolliculoma as a pole of the spectrum of trichosebo-folliculoma.¹⁵⁹ This entity is discussed here because the sebaceous elements are usually the most prominent feature.

Lesions on the face are usually excised or shaved. The giant variant described on the scrotum was successfully treated by CO₂ laser and acitretin therapy.⁶⁰⁴

Histopathology

The lesion is composed of infundibular structures, sometimes cystic, with numerous radiating sebaceous lobules. Occasional rudimentary

Figure 33.31 Folliculosebaceous cystic hamartoma. Radially arranged sebaceous lobules are attached to an infundibulocystic structure. (H&E)

hair structures and even apocrine glands may be present (**Fig. 33.31**). The pilosebaceous units are embedded in a mesenchymal stroma composed of variable proportions of fibrous, adipose, vascular, and neural tissue (**Fig. 33.32**). There are usually spindle-shaped cells in the stroma, and some of these stain for CD34 or factor XIIIa.⁵⁹⁸ Smooth muscle was the only mesenchymal component in one case, leading to the diagnosis of **folliculosebaceous smooth muscle hamartoma**.⁶⁰⁷

Differential diagnosis

The unique constellation of features usually allows distinction of folliculosebaceous cystic hamartoma from other sebaceous neoplasms. The case reported with a prominent neural component in the stroma has some features in common with the neurofollicular hamartoma (see p. 921), although this latter entity lacks the haphazard cystic infundibular structures.⁴⁹³ The morphologically related sebaceous trichofolliculoma (see p. 911) lacks a mesenchymal stromal component,⁶⁰¹ whereas conventional trichofolliculoma differs by the presence of secondary follicles.⁶⁰⁸ Note that not all authors agree with the concept that folliculosebaceous cystic hamartoma represents a late stage of trichofolliculoma.⁶⁰⁵ In this regard, Misago and co-workers suggested that the upregulation of nestin expression in lesions of folliculosebaceous cystic hamartoma might explain its unique mesenchymal changes, which are not appreciated in trichofolliculoma.⁶⁰⁹ Nestin is an intermediate filament protein expressed in follicle stem cells in the bulge region of the

Figure 33.32 Folliculosebaceous cystic hamartoma. The surrounding mesenchymal stroma contains fibrous, vascular, and neural tissue. Scattered spindle cells are identified. (H&E)

hair follicle, and its actions may result in the production of various mesenchymal and neural tissues.

BENIGN SEBACEOUS TUMORS

The four tumors in this category are sebaceous adenoma, sebaceoma, mantleoma, and reticulated acanthoma with sebaceous differentiation. Because sebaceous tumors are an important component of the Muir–Torre syndrome, it is considered here also.

SEBACEOUS ADENOMA

The sebaceous adenoma is an uncommon benign tumor that usually presents as a slowly growing, pink or flesh-colored solitary nodule, predominantly on the head and neck of older individuals.⁶¹⁰ Rarely, it may involve the buccal mucosa⁶¹¹ or penis.⁶¹² Sebaceous adenomas are usually approximately 0.5 cm in diameter, but larger variants, up to 9 cm in diameter, can develop. Occasionally, they ulcerate and bleed or become tender. Sebaceous adenomas, either solitary or multiple, may be associated with visceral cancer, usually of the gastrointestinal tract – the Muir–Torre syndrome (see later).

Ackerman suggested that sebaceous adenoma is really a carcinoma.⁶¹³ However, the evidence for this is not convincing. Recent immunohistochemical studies also provide no support for this view.⁶¹⁴

Treatment is usually by excision or shave biopsy.

Histopathology⁶¹⁰

The tumor is composed of multiple sharply circumscribed sebaceous lobules separated by compressed connective tissue septa. It is usually centered on the mid dermis, but it may adjoin the epidermis or exhibit multiple openings onto the skin surface, with partial replacement of the epidermis by basaloid epithelium showing sebaceous differentiation (Fig. 33.33). The sebaceous lobules have a peripheral germinative layer of small basaloid cells, with mature sebaceous cells centrally and transitional forms in between. This maturation is not as orderly or as well-developed as in normal sebaceous glands. Nevertheless, mature cells still outnumber the darker germinative cells.²⁷⁰ There is variable central holocrine degeneration, with granular debris scattered in the

Figure 33.33 Sebaceous adenoma. The sebaceous lobules have a peripheral layer of smaller basaloid cells. (H&E)

area of cystic change. Cystic sebaceous tumors are now regarded as a marker for the mismatch repair-deficient subtype of the Muir–Torre syndrome. The connective tissue stroma may contain a patchy chronic inflammatory cell infiltrate. An overlying cutaneous horn is a rare occurrence.⁶¹⁵ The term ‘**steatosebocystadenoma**’ has been used for a sebaceous adenoma arising in the wall of a steatocystoma simplex.⁶¹⁶

On immunohistochemistry, CD10 staining of the cytoplasmic membrane occurs in nearly half of the cases.⁶¹⁷ CK15 is expressed in the basal cells; it is also present in other sebaceous tumors and sebaceous hyperplasia.⁶¹⁸

Differential diagnosis

The differential diagnosis of sebaceous adenoma includes other sebaceous tumors and tumor-like proliferations, basal cell carcinoma with sebaceous differentiation, and sebaceous carcinoma. The expansion of basaloid cells is a key feature in distinguishing this lesion from sebaceous hyperplasia.⁵⁶¹ In addition, lesions associated with the Muir–Torre syndrome show a degree of disorganization not encountered in sebaceous hyperplasia. Sebaceoma (see subsequent discussion) has a greater proportion of basaloid cells and may also show some features in common with trichoepithelioma, dermal duct tumor, cylindroma, and trichilemmoma. Basal cell carcinoma with sebaceous differentiation can show considerable histopathologic overlap with sebaceous adenoma, but it shows a higher proportion of basaloid cells (>50% of the total cell population), a fibromyxoid stroma, and clefting artifact separating tumor lobules from the adjacent stroma. In connection with the argument that sebaceous adenoma is really a carcinoma, sebaceous adenomas lack the degree of cytologic atypia and infiltrative growth pattern frequently observed in sebaceous carcinomas, although there may be circumscription and even peripheral palisading of tumor islands in the *basaloid* variant of sebaceous carcinoma.

SEBACEOMA

The term ‘sebaceoma’ was coined by Ackerman for a distinctive sebaceous tumor,⁶¹⁹ examples of which have been reported in the past as basal cell carcinoma with sebaceous differentiation⁶¹⁰ or sebaceous epithelioma.^{270,620} These tumors are usually solitary, flesh-colored to yellowish papulonodules on the face or scalp, but they are sometimes multiple, particularly in the Muir–Torre syndrome (discussed previously), or associated with organoid nevi.⁶¹⁰ Sebaceoma of the external ear canal has been reported.⁶²¹ They measure 0.5–3 cm in diameter

Figure 33.34 Sebaceoma. (A) Sheets of basaloid cells are randomly admixed with small sebocytes and sebaceous ducts. (B) Another case. The inset shows the cells in more detail. (H&E)

and tend to occur in older adults, although they may be seen in younger adults as well. They grow slowly and do not usually recur after treatment.

Histopathology^{610,619}

There are multiple nests of basaloid cells with a random admixture of sebaceous cells, either solitary or in clusters (Fig. 33.34). The tumor is centered on the upper and mid dermis, but some nests may be continuous with the basal layer of the epidermis. The small basaloid cells of the tumor outnumber the mature sebaceous component. Cysts and duct-like structures containing the debris of holocrine degeneration may be present.⁶²⁰ There are scattered mitoses, but the tumor lacks the atypia of sebaceous carcinoma.

The sebaceoma can exhibit an amazing diversity of patterns.⁵⁴⁹ Sebocytes and sebaceous ducts may be plentiful or scarce, and the sebocytes may show variable vacuolation. Apocrine differentiation has also been reported.^{622,623} Adenoid, reticulated, cribriform, cystic, and cornified areas may be present.^{624,625} A rippled or carcinoid-like architecture in the basaloid component has also been described.^{561,626} The cytokeratin expression in this variant (CK19) indicates an undifferentiated and

pluripotent component.^{627,628} Trichoblastoma can also have a rippled pattern,⁶²⁹ although Ackerman believes this pattern is always indicative of a sebaceoma.⁶³⁰ Sometimes, areas resembling a seborrheic keratosis with sebaceous differentiation may be present.⁶³¹ Furthermore, a sebaceoma has been reported arising in association with a seborrheic keratosis.⁶³² Such cases merge with the variant of sebaceoma with surface changes of verruca/seborrheic keratosis.⁶³³

There exist tumors with close morphological resemblance to basal cell carcinoma that may show focal sebaceous differentiation. Such tumors are best classified as basal cell carcinomas with sebaceous differentiation. It is acknowledged that there is some overlap of this tumor with what has been designated sebaceoma,⁶¹⁹ but this basal cell carcinoma variant shows peripheral basal cell palisading, and sometimes tumor-stroma separation, and a loose fibromucinous stroma.⁵⁶¹ Rare variants have been reported with sweat gland differentiation in part of the lesion.⁶³⁴

Differential diagnosis

CK7 is present in most sebaceous tumors, but it is usually absent in basal cell carcinomas.⁵⁶¹ Sebaceous cells express EMA but not carcinoembryonic antigen (CEA). Only mature sebaceous cells express EMA, not the germinative cells. In contrast, expression of EMA is uncommon in basal cell carcinomas; they invariably express Ber-EP4, whereas sebaceomas do not.⁶³⁵ Sebaceomas express CK15, and D2-40 in the basaloid, germinative cells.^{548,636} A possible differential diagnostic problem could arise in distinguishing between rippled-pattern sebaceoma and the rippled-pattern sebaceous trichoblastoma. Graham and Barr suggested that sebaceomas are often smaller, better circumscribed lesions with connections to the overlying dermis and featuring both vacuolated and nonvacuolated sebocytes.⁴⁰⁷ No association with the Muir-Torre syndrome was seen in the three reported cases.⁴⁰⁷ Recent work suggests the differential diagnostic value of immunohistochemical staining for the lipid synthesis and processing proteins α/β hydroxylase domain-containing protein 5 (ABHD5), progesterone receptor membrane component-1 (PGRMC1), and squalene synthase (SQS). Clear cell basal cell carcinomas are negative for these markers. Sebaceous carcinomas show dispersed cytoplasmic, punctate, or vesicular staining for ABHD5 and vesicular and membranous staining for PGRMC1 and SQS. In sebaceomas, these stains highlight the tightly clustered lipid vacuoles found in sebocytes.⁶³⁷

MUIR-TORRE SYNDROME

Muir-Torre syndrome (OMIM 158320), the first examples of which were reported in 1967,⁶³⁸ is characterized by the development of sebaceous tumors, often multiple, in association with visceral neoplasms, usually gastrointestinal carcinomas.⁶³⁹⁻⁶⁴⁷ Keratoacanthomas, epidermal cysts, and colonic polyps may also be present.⁶⁴⁸ The sebaceous tumors are sometimes difficult to classify,⁶⁴⁹ but they most resemble either sebaceous adenoma or sebaceoma, and occasionally sebaceous carcinoma.⁶⁵⁰⁻⁶⁵² Multiple sebaceous tumors and sebaceous tumors occurring before the age of 50 years are strong indicators of the syndrome.⁶⁵³ Sebaceous hyperplasia may also be present,⁶⁵⁴ but most reports have indicated that sebaceous hyperplasia is not indicative of Muir-Torre syndrome.⁶⁵⁵ The cutaneous tumors may precede or follow the first direct manifestation of the visceral cancer, and they may occur sporadically in other family members.⁶⁵⁶ The sebaceous neoplasms generally develop after the visceral cancer.⁶⁵⁷ The visceral tumor is usually of the gastrointestinal tract, particularly adenocarcinoma or polyps of the large bowel (see later), but other sites, such as the larynx, the genitourinary system in men,⁶⁵⁸ and the ovary and uterus, may be involved.⁶⁵⁹ Lymphoma has been reported. The visceral tumors may behave in a less aggressive manner than would be expected

from the histology.^{639,660,661} This is particularly so for tumors displaying widespread microsatellite instability (MSI).⁶⁶⁶ Detection of MSI in cutaneous tumors of various types may form the basis of a non-invasive screening technique for hereditary nonpolyposis colon syndrome (Lynch syndrome), of which the Muir–Torre syndrome is regarded as an allelic variant.^{662–666} It represents 1 or 2% of cases of Lynch syndrome. Immunosuppression may unmask a latent Muir–Torre syndrome phenotype, particularly in transplant recipients.⁶⁶⁷

The Muir–Torre syndrome is inherited as an autosomal dominant trait. Mutations in one of the DNA mismatch repair genes *MLH1*, *MSH2*, and *MSH6* have been found in these patients.^{668,669} Mutations in *MSH2* account for the majority (90%) of cases,⁶⁷⁰ whereas *MSH6* mutations are limited to a few cases.⁶⁷¹ *PMS2* mutations have not been reported so far in the Muir–Torre syndrome, but they have been in the Lynch syndrome. A colleague of the author has seen two such cases in the Muir–Torre syndrome. *MSH6* and *PMS2* mutations are said to be associated with a milder phenotype than mutations in the other two genes.⁶⁷¹ Although most abnormalities involve gene deletions, partial duplication of the *MSH2* gene has resulted in truncation of the gene product and a nonfunctional state.⁶⁵⁵ The sebaceous tumors may show widespread MSI.⁶⁶⁹ In one study, loss of one of the mismatch repair genes (either *MSH2* or *MLH1*) was found in 80% of the benign sebaceous lesions associated with visceral malignancy but in only 23% of sebaceous lesions not associated with visceral malignancy.⁶⁵⁴ A more recent study found no difference in the incidence of mutations in the mismatch repair genes in these two groups.⁶⁷² Overlap between Muir–Torre and Turcot's syndrome has been reported on several occasions.^{673,674} Turcot's syndrome consists of colorectal adenomas, without polyposis, and central nervous system neoplasms. Patients with Turcot's syndrome type I have had mutations in the *MLH1*, *MSH2*, and *PMS2* genes, but they mainly have mutations in *MLH1* and *PMS2*.⁶⁷⁵ It has been suggested that treatment with isotretinoin and interferon- α -2a can prevent tumor development.⁶⁴⁷

Histopathology^{639,649}

The sebaceous tumors resemble to varying degrees those already described.⁶⁷⁶ Often, they appear 'unique' and difficult to classify.^{649,653} There may be solid sheets of basaloid cells in some lobules or an intermingling of these cells and sebaceous cells without any orderly maturation. It has been suggested that these atypical features are predictive of malignant transformation, if not completely removed.⁶⁷⁷ Sometimes the tumors resemble a basal cell carcinoma but with focal sebaceous differentiation. Mucinous and cystic areas may be present (Fig. 33.35). Cystic lesions are an important component of this syndrome (discussed previously).⁶⁷⁸ Other tumors may connect with the surface and have a central debris-filled crater resembling, in part, a keratoacanthoma. Typical keratoacanthomas also occur. The lesion reported as a keratoacanthoma-like squamous cell carcinoma on the basis of its venous invasion was probably a keratoacanthoma with venous invasion.⁶⁷⁹ All sebaceous tumors should be screened for the presence of MSH-2, MSH-6, MLH-1, and PMS-2, the respective gene products of *MSH2*, *MSH6*, *MLH1*, and *PMS2*. The diagnosis of Muir–Torre syndrome is made when nuclear staining for the particular gene product is absent in the tumors.⁶⁸⁰ Because MSH-2 and MSH-6 proteins normally form a stable heterodimer, mutations in the *MSH2* gene can produce an instability of this heterodimer, with secondary lack of expression of MSH-6 protein.⁶⁵⁷ False-positive and -negative results are uncommon.⁶⁸¹

The cells express epithelial membrane antigen and nuclear androgen receptor.⁶⁸²

On dermoscopy, sebaceous adenomas and sebaceomas associated with Muir–Torre syndrome show similar findings. Those with central craters have elongated radial telangiectasias with an opaque, structureless ovoid white-yellow center (representing aggregates of enlarged sebaceous glands),

Figure 33.35 Cystic sebaceous adenoma in a patient with Muir–Torre syndrome. (H&E)

sometimes with overlying blood crusts; those without a central crater show arborizing vessels over a white-yellow background and loosely arranged yellow, comedo-like globules.⁶⁸³ Reflectance confocal microscopy of sebaceous adenomas shows aggregates of ovoid cells with dark nuclei and bright, refractile glistening cytoplasm (sebaceous cells), surrounded by a rim of basaloid cells.⁶⁸³

RETICULATED ACANTHOMA WITH SEBACEOUS DIFFERENTIATION

Reticulated acanthoma with sebaceous differentiation is the term used for a rare tumor with a predilection for the face of elderly individuals. It is usually solitary,⁶⁸⁴ but multiple papules have been recorded.⁶⁸⁵ It behaves in a benign manner.⁶⁸⁶ It was previously called superficial epithelioma with sebaceous differentiation, but Steffen and Ackerman believed that the use of the word 'epithelioma' may give an impression of malignancy and suggested the alternative title used here.⁵⁴⁹ The lesions sometimes discharge yellowish material. Sánchez Yus and colleagues suggested that the term 'sebomatricoma' should be applied to all benign neoplasms with sebaceous differentiation.^{687,688} The six cases

Figure 33.36 Reticulated acanthoma with sebaceous differentiation. This lesion features proliferation of squamoid and basaloid cells (the latter near the base of the lesion) with broad attachments to the overlying epidermis. Clusters of mature sebaceous cells are present within the deeper portions of the lesion. This example is not as 'plate-like' as some lesions. (H&E)

described by LeBoeuf and Mahalingam under the title 'acanthomatous superficial sebaceous hamartoma' apparently represent superficial epithelioma with sebaceous differentiation.⁶⁸⁹ A recent example of this tumor was found in a patient with Muir–Torre syndrome; reduced expression of MSH6 protein was noted in the lesion.⁶⁹⁰

Histopathology

The tumor is characterized by a superficial plate-like proliferation of basaloid to squamoid cells with broad attachments to the overlying epidermis.⁶⁸⁴ Clusters of mature sebaceous cells are present within the tumor (**Fig. 33.36**). In one case, the tumor showed homogeneous staining for CK14 but no staining for CK10, involucrin, or filaggrin. CK7 and epithelial membrane antigen stained only aggregates of sebocytes and ducts.⁶⁹¹ The low-power pattern is somewhat analogous to that seen in basaloid follicular hamartoma, an entity that lacks sebaceous differentiation.⁶⁹² There is also some resemblance to seborrheic keratosis, but it lacks pigment and horn cysts, and infundibular tunnels stuffed with cornified cells are rare.⁶⁹³

Dermoscopy has shown irregular pigmentation, with bright yellow dots in a linear or reticular arrangement. Dotted and comma-like vessels were also identified.⁶⁹⁴

MANTLEOMA

The mantleoma is a tumor of the sebaceous mantle, a neglected structure that gives rise to sebaceous glands. The mantle is composed of cords of basaloid cells that hang downwards from the side of

Figure 33.37 Mantleoma. This lesion features prominent follicular mantles composed of cords of basaloid cells that hang downwards from the sides of follicular infundibula. The cords can be seen to contain sebaceous cells. Other less well-developed folliculosebaceous structures can be seen in the vicinity. (H&E)

the follicular infundibulum like a skirt. Unfortunately, the term 'mantleoma' has been used for two different lesions. It has been applied by Steffen to a small, incidental tumor on the face and is described later.⁶⁹⁵ It was also used in the book by Steffen and Ackerman for what is often called a fibrofolliculoma.⁵⁴⁹

Histopathology

The mantleoma consists of cords and columns of undifferentiated cells that radiate from the infundibulum of a hair follicle (**Fig. 33.37**). The cords may interweave into a retiform pattern. Varying degrees of vacuolization of the cells, representing sebocyte formation, can be seen. Some sebaceous ductal structures may be present.⁶⁹⁵

The **folliculocentric basaloid proliferation** of Leshin and White⁶⁹⁶ is a hyperplasia of mantle epithelium that may become so pronounced that the term 'mantleoma' would be appropriate (**Fig. 33.38**). It would probably be best to regard the two as variants of the same lesion. It may be confused with basal cell carcinomas, particularly on frozen section. It is a common and largely neglected entity.

TUMORS WITH FOCAL SEBACEOUS DIFFERENTIATION

This category is included for completeness so that tumors considered in other sections of this book can be grouped together. Sebaceous differentiation or sebaceous glands can be seen in the following:

- Basal cell carcinoma
- Squamous cell carcinoma
- Trichoblastoma
- Seborrheic keratosis
- Verruca vulgaris
- Inverted follicular keratosis
- Dermatofibroma
- Reticulated acanthoma
- Apocrine poroma with sebaceous differentiation.

The occurrence of basal cell carcinomas with sebaceous differentiation was mentioned previously. Sebaceous differentiation is very rare in

Figure 33.38 (A) Mantleoma (folliculocentric basaloid proliferation). (B) This is a very large lesion found incidentally in the re-excision specimen of a previously removed melanoma. Basaloid cells, sebocytes, and ducts are present. (H&E)

squamous cell carcinomas, and such cases must be distinguished from sebaceous carcinomas and from invasive Bowen's disease.

The *trichoblastoma with sebaceous differentiation* is characterized by sebocytes and sebaceous duct-like structures within the basaloid aggregations of a large nodular type of trichoblastoma.⁶³³

The *seborrheic keratosis with sebaceous differentiation* usually has recognizable areas of seborrheic keratosis with admixed sebocytes occurring in clusters or as single cells. Microcysts with variable resemblance to sebaceous ducts are usually present.⁵⁴⁹ They are much smaller than the horn cysts of a seborrheic keratosis. There is some overlap with apocrine poroma with sebaceous differentiation.⁶⁹⁷ There is also a rare variant of sebaceoma in which the dermal nests are connected to hyperplastic infundibula. There is a proliferation of infundibular keratinocytes (basaloid cells and/or squamous cells) associated with hypergranulosis and tunnels of cornified cells mimicking verruca or seborrheic keratosis.⁶³³ The sebaceous component is much larger in this variant of sebaceoma than it is in the seborrheic keratosis with sebaceous differentiation.

The *verruca vulgaris with sebaceous differentiation* is a rare entity. Sometimes, focal apocrine differentiation is also present. Several of the cases pictured in the excellent book by Steffen and Ackerman⁵⁴⁹ would be regarded by many as examples of *inverted follicular keratosis*. The induction of folliculosebaceous units by *dermatofibromas* is

mentioned elsewhere (see p. 994). The *reticulated acanthoma with sebaceous differentiation* is the term used by Steffen and Ackerman for what others have called superficial epithelioma with sebaceous differentiation (see p. 928). The *apocrine poroma with sebaceous differentiation* (sebocrine adenoma) at first glance resembles an eccrine poroma, but the epithelial proliferations show apocrine and sebaceous differentiation.^{698–700} Sebaceous duct-like structures are observed within the basaloid aggregations.⁶³³ A similar case with prominent cystic degeneration has been reported.⁷⁰¹

MALIGNANT SEBACEOUS TUMORS

Although some tumors, particularly basal cell carcinomas, may show focal sebaceous differentiation, the sebaceous carcinoma is the only 'pure' tumor in this category.

SEBACEOUS CARCINOMA

Sebaceous carcinomas have traditionally been considered in two groups: those arising in the ocular adnexa, particularly the meibomian glands and glands of Zeiss, and tumors arising in extraocular sites.^{702,703} The latter are less common and are usually found as yellow-tan firm nodules, often ulcerated, measuring 1–4 cm or more in diameter. They account for approximately 20% of all sebaceous carcinomas, but this figure varies in different countries. They are found particularly on the head and neck of elderly patients. Rare sites include the leg,⁷⁰⁴ foot,⁷⁰⁵ nipple,⁷⁰⁶ labia,^{610,707} and penis.⁷⁰⁸ Extraocular tumors are exceedingly rare in children.⁷⁰⁹

Those arising in the ocular adnexa are more common and comprise 1% of all eyelid neoplasms. They have a slight female preponderance and tend to involve the upper eyelid more than the lower.^{710,711} They are rare in children.⁷¹² They often masquerade clinically as a chalazion, delaying effective treatment. A cutaneous horn is rarely present.⁷¹³ Rarely, there is a history of irradiation to the area.⁷¹¹ Up to one-third develop lymph node metastases, usually to the preauricular and cervical nodes, and there is a 20% 5-year mortality rate. Extraocular cases with nodal and even visceral metastases have been reported, leading the authors to question the notion that extraocular tumors are less aggressive than sebaceous carcinomas of the eyelid.^{708,714} Further examples of aggressive extraocular sebaceous carcinoma have been documented.⁷¹⁵

Rarely, sebaceous carcinomas are associated with the Muir–Torre syndrome (discussed previously),⁷⁰² organoid nevi (nevus sebaceus),^{716,717} organ transplant recipients,⁷¹⁸ or rhinophyma.⁷¹⁹

Wide surgical excision is the treatment of choice. Mohs micrographic surgery has been used with excellent results,⁷²⁰ but no large series has been published. Adjuvant radiotherapy has been used, particularly for those with metastatic disease, but also for highly infiltrative or large tumors.⁷²¹ Neck dissection is used for operable cases of the eyelid, with regional lymph node metastases. Sentinel node biopsy for sebaceous carcinomas is subject to further study.⁷²² There is no published information on the best choice of chemotherapeutic agents for metastatic sebaceous carcinomas.⁷²² Because there are defects in the expression of retinoid acid receptors in sebaceous carcinomas, it is possible that this may affect the potential response of this tumor to retinoid therapy.⁷²³

Histopathology^{610,711}

The tumor is composed of lobules or sheets of cells separated by a fibrovascular stroma. The cells extend deeply and often involve the subcutaneous tissue and even the underlying muscle. There is infiltration at the edges. The cells show variable sebaceous differentiation, manifest as finely vacuolated or foamy rather than clear

Figure 33.39 (A) Sebaceous carcinoma. (B) Vacuolated sebaceous cells are present. (H&E)

cytoplasm (**Fig. 33.39**). In one study, 48% of the cases had cytoplasmic vacuoles.⁷²⁴ There is usually more differentiation at the center of the nests. The nuclei are large, with large nucleoli. There are scattered mitoses. Smaller basaloid cells and cells resembling those in a squamous cell carcinoma may be present; even focal keratinization does not negate the diagnosis. Less than 10% of cases resemble in some way a basal cell carcinoma.⁷²⁴ Focal necrosis is not uncommon, and this may have a ‘comedo-like’ pattern.⁷²⁴ Sometimes pseudoglandular formation occurs. The vacuolated cells show abundant lipid if a frozen section is stained with oil red O or Sudan black. There may be a very small amount of PAS-positive diastase-resistant material in some cells. Focal apocrine differentiation is sometimes present.^{622,725} This is not surprising in view of the common embryological origin of the folliculosebaceous–apocrine unit. A carcinoid-like pattern is another rare histological variant.⁶²⁶ It has also been reported in sebaceomas.⁶²⁶

The periocular lesions often show a pagetoid or, less commonly, a carcinoma *in situ* change in the overlying conjunctiva or epidermis of the eyelid (**Fig. 33.40**).^{710,711} This feature was seen in one-third of all cases in one series.⁷²⁴ Such changes are not usually seen in extraocular cases. The presence of such a change above extraocular tumors should prompt reassessment of the lesion in case it is invasive Bowen’s disease, which may rarely mimic sebaceous carcinoma.⁷²⁶ On the other hand, it is easy to misdiagnose intraepithelial sebaceous carcinoma of the eyelid as Bowen’s disease. Sebaceous carcinoma should be considered

Figure 33.40 Sebaceous carcinoma. There is early epidermotropism. (H&E)

for any lesion of the upper eyelid or if multivacuolated cytoplasmic clear cell changes are seen.⁷²⁷

Adverse prognostic features for tumors of the ocular adnexa include vascular and lymphatic invasion, orbital extension, poor differentiation, an infiltrative growth pattern, and large tumor size.⁷¹¹

Immunohistochemically, the tumor cells show positive reactions for EMA and androgen receptor (AR) but not for CEA, S100 protein, or gross cystic disease fluid protein-15 (GCDFFP-15).⁷²⁸ CAM5.2 and BRST-1 have also been positive.⁷²⁴ In one report, two cases reacted with CD36.⁷²⁹ Note that EMA staining is often absent in poorly differentiated tumors but nuclear staining for AR is present, making it the more reliable marker.⁶⁸² Approximately 60% of basal cell carcinomas show focal positivity for AR.⁶⁸² An immunohistochemical review concluded that an EMA-positive, Ber-EP4-positive immunophenotype supports sebaceous carcinoma; an EMA-positive, Ber-EP4-negative profile supports squamous cell carcinoma; and an EMA-negative, Ber-EP4-positive result supports basal cell carcinoma.⁷³⁰ Ocular sebaceous carcinomas contain CK7, but ocular basal cell carcinomas and squamous cell carcinomas do not.^{731,732} Basaloid and undifferentiated cells express the keratin 15 (CK15) stem cell marker.⁶¹⁸ CK19 requires further study before its use can be assessed.^{627,733} Sebaceous carcinomas express statistically significant, increased levels of p53 and Ki-67 compared to benign lesions and reduced levels of bcl-2 and p21 compared to adenomas.⁶¹⁴ Survivin, an inhibitor of apoptosis, is expressed more often in sebaceous carcinomas than adenomas and hyperplasia, but because the number of cases expressing this protein is low, it is not of any diagnostic use.⁷³⁴ Bcl-X appears to be a marker of sebocytes.⁷³⁵ Telomerase expression occurs in all sebaceous neoplasms and is of no value in distinguishing adenomas from carcinomas.⁷³⁶

Diagnosis can be aided by cytology of skin scrapings. Findings include polygonal cells with pleomorphic hyperchromatic nuclei, arranged singly, in clusters, and in acinar patterns. The cytoplasm of these cells contains multiple microvacuoles. These are found on a clear background with a few lipid vacuoles.⁷³⁷

Electron microscopy

The tumor cells contain cytoplasmic lipid droplets and tonofilaments that insert into well-formed desmosomes.^{708,710}

Differential diagnosis

The histopathologic differential diagnosis of sebaceous carcinoma is broad and includes other malignant (and some benign) clear cell tumors of skin. This is particularly the case because poorly differentiated sebaceous carcinoma may display only rudimentary sebaceous

differentiation, and cytoplasmic vacuolization may therefore be difficult to discern. Entities that should be considered are squamous cell carcinoma with clear cell features; basal cell carcinoma with sebaceous differentiation and clear cell basal cell carcinoma; trichilemmal carcinoma; balloon cell melanoma; clear cell sarcoma extending into the dermis; and metastatic clear cell carcinomas from other sites, particularly metastatic renal cell carcinoma (one of the metastatic tumors that can appear in skin before detection of the primary lesion). EMA can be helpful in identifying intracytoplasmic vesicles in some cases. Sebaceous carcinomas also lack several protein products that are identified in sweat gland tumors or metastatic carcinomas, including carcinoembryonic antigen, S100 protein, GCDFP-15, cancer antigen 125 (CA-125), CA-19-9, or the renal cell carcinoma marker.

A possible pitfall in diagnosis can result from the use of adipophilin, which stains cells of renal cell carcinoma as well as sebaceous carcinoma.^{738,739} However, the staining pattern in nonsebaceous tumors tends to be granular rather than membranous-vesicular.⁷³⁸ Basal cell carcinoma can be confused with basaloid sebaceous carcinoma. However, basal cell carcinoma with sebaceous differentiation tends to show a higher degree of sebaceous differentiation than is the case in sebaceous carcinoma. Other basal cell carcinomas may also show clear cell change, but the nuclei of basal cell carcinomas are not as vesicular as those in sebaceous carcinomas. In contrast to sebaceous carcinoma, the stroma of basal cell carcinoma is fibromyxoid in type. Both tumors can express BerEp4, but EMA staining is negative in basal cell carcinoma except for any areas that might show clear-cut sebaceous differentiation.

Another problem that arises is the distinction between sebaceous carcinoma with squamoid features and conventional squamous cell carcinoma. Here, BerEp4 can be helpful because sebaceous carcinoma is positive for this marker, whereas squamous cell carcinoma is negative. Androgen receptor staining is positive in sebaceous carcinomas and negative in squamous cell carcinomas; however, approximately one-third of basal cell carcinomas show focal nuclear reactivity with this method.⁷⁴⁰ As noted previously, immunohistochemical staining for the lipid synthesis and processing proteins ABHD5, PGRMC1, and SQS can be of help because clear cell basal cell carcinomas are negative for these markers, whereas sebaceous carcinomas show dispersed cytoplasmic, punctate or vesicular staining for ABHD5, and vesicular and membranous staining for PGRMC1 and SQS.⁶³⁷ Sarcomatoid sebaceous carcinoma can be distinguished from true sarcoma by its keratin positivity, but it may be difficult to recognize the tumor as specifically sebaceous if sebocytic differentiation cannot be recognized. Sebaceous differentiation can sometimes be encountered in other malignancies, including microcystic adnexal carcinoma,⁷⁴¹ lymphoepithelioma-like carcinoma,⁷⁴² and difficult-to-classify adnexal carcinomas with divergent differentiation;⁷⁴³ the mere finding of sebaceous cells in these circumstances should not lead to a diagnosis of sebaceous carcinoma in the absence of other attributes of that tumor.

SWEAT GLAND TUMORS

Normal apocrine glands

Apocrine glands, which are derived from the folliculosebaceous-apocrine germ, are restricted to the axillae, anogenital and inguinal regions, the periumbilical and periareolar regions, and, rarely, the face and scalp. Specialized apocrine glands are found on the eyelids (the glands of Moll) and in the auditory canal (ceruminous glands). The breast is sometimes regarded as a modified apocrine gland.

Apocrine glands are composed of a secretory coil in the lower dermis and subcutis, a straight ductal component that is indistinguishable from the eccrine duct, and a terminal intra-infundibular duct that opens into the follicular infundibulum. A conspicuous feature of

apocrine secretory cells is their 'decapitation' mode of secretion whereby an apical cap, formed at the luminal border of the apocrine cells, separates off from the cell and is discharged into the lumen. Apocrine secretions produce a characteristic odor.⁷⁴⁴

Sclerosing adenosis, similar to the lesion of the breast, has been reported in apocrine glands of the scalp.⁷⁴⁵

Alternate classification

Despite the relative paucity of apocrine glands in comparison with the ubiquitous eccrine gland, found everywhere in the skin, it seems that many tumors arising in non-apocrine areas, and formerly regarded as being of eccrine origin, are probably apocrine in type. This reclassification of some tumors has taken place as a consequence of the identification of decapitation secretion, either as a regular or as an occasional feature, and the presence of, or association with, cells or other tumors showing follicular and/or sebaceous differentiation. The rationale is their common embryological origin from the folliculosebaceous-apocrine germ.

Using these and other criteria, Requena, Kiryu, and Ackerman reclassified as apocrine the following tumors that were previously regarded as being of eccrine type:⁷⁴⁶

- Eccrine hidrocystoma
- Papillary eccrine adenoma
- Hidradenoma (nodular, cystic)
- Cyndroma
- Spiradenoma
- Syringoma
- Poromas (some)
- Malignant variants of the above
- Microcystic adnexal carcinoma
- Mucinous carcinoma
- Signet-ring cell carcinoma
- Adenoid cystic carcinoma.

This classification is likely to be regarded in some centers as controversial. Cynics will argue (1) does it matter whether they are called eccrine or apocrine, particularly when the ducts of either gland are indistinguishable, and (2) can the folliculosebaceous-apocrine germ be so unstable that it produces apocrine tumors at sites not normally frequented by apocrine glands? Immunohistochemical markers such as lysozyme, Leu M1, and GCDFP-15 (AP-15, Brst-2)⁷⁴⁷ are no longer regarded as being of much assistance in this debate.⁷⁴⁸ Newer markers are offering some support for Ackerman's views.

Of interest are the results obtained using a novel monoclonal antibody, IKH-4, which stains the eccrine secretory coil but not the apocrine secretory segment.⁷⁴⁹ Unfortunately, specific markers have a habit in dermatopathology of becoming less specific with time, and subsequent studies do not invariably confirm the initial ones. Notwithstanding these reservations, the study mentioned found staining that would support an eccrine origin for hidradenoma, poroma, spiradenoma, cyndroma, syringoma, and eccrine carcinoma and the occurrence of an eccrine variant of hidrocystoma, papillary adenoma, and syringocystadenoma papilliferum.⁷⁴⁹ These tumors have also stained with the eccrine gland-associated monoclonal antibodies EKH-5 and EKH-6.⁷⁴⁹ However, the association of cyndromas and spiradenomas with trichoepitheliomas in the Brooke-Spiegler syndrome is compelling evidence for their apocrine origin.

In light of these studies, various changes have been made in the traditional subdivision of eccrine and apocrine tumors.

Apocrine versus eccrine differentiation

In the past, there has been some debate regarding the eccrine or apocrine origin and differentiation of certain adnexal tumors.

Histochemistry and electron microscopy sometimes gave conflicting results, with features suggestive of both apocrine and eccrine differentiation in some tumors. The recent development of various monoclonal antibodies, for use with immunoperoxidase techniques, has assisted marginally in the classification of the various adnexal tumors.⁷⁵⁰⁻⁷⁵³ The various markers have not lived up to initial expectations. The first of these markers to have diagnostic value was the finding of CEA in sweat gland tumors.⁷⁵⁴ This does not represent a single oncofetal antigen but comprises a family of homologous glycoproteins that includes classic CEA-180, biliary glycoprotein (BGP), and nonspecific cross-reacting antigens (NCA). If these monospecific antibodies are used, a rather consistent profile emerges: staining for both CEA-180 and NCA indicates ductal differentiation of both apocrine and eccrine type; coexpression of all three is consistent with differentiation toward the secretory portion of eccrine glands or the transitional portion of proximal ducts.⁷⁵⁵

Other monoclonal antibodies have been developed with variable specificity and sensitivity for eccrine-related antigens. They include the following:

1. SKH1, which reacts with the secretory portion and coiled duct of the eccrine gland and the secretory portion of apocrine glands⁷⁵⁶
2. Ferritin antibody, which demonstrates ferritin in the outermost layer of the eccrine and apocrine duct⁷⁵⁷
3. Antibodies to IgA and secretory component, which detect antigen in the lumen and on the surface of the epithelium of sweat glands⁷⁵⁸
4. IKH-4, EKH-5, and EKH-6, which stain the eccrine secretory coil⁷⁴⁹
5. Dako-CK1 and CAM5.2 (both commercially available), which react with two cytokeratins of different molecular weight.⁷⁵⁹

Whereas Dako-CK1 detects a cytokeratin in the intraepidermal eccrine duct and the inner layer of the intradermal portion of the duct but not other structures, CAM5.2 reacts with the apocrine gland and supposedly the duct, and the eccrine secretory coils but not the eccrine duct.⁷⁵⁹ Numerous other monoclonal antibodies have been prepared to various cytokeratins.

The monoclonal antibody MNF116, which detects the low- and intermediate-molecular-weight keratins (5, 6, 8, 17, and 19), stains the basal cells of the epidermis and adnexae. It is found in all epithelial tumors, including adnexal ones.⁷⁶⁰ Antibodies to individual keratins have not been of much assistance in routine diagnosis, but they have given valuable insight into the possible derivation and/or differentiation of various eccrine tumors.^{216,761,762} For example, syringomas exhibit a pattern similar to normal dermal eccrine ducts (EMA in peripheral cells, CK10 in intermediate cells, and CK6, CK19, and CEA in luminal cells), and eccrine poromas exhibit a widespread reaction for CK5/6 and EMA, analogous to peripheral dermal duct cells.²¹⁶ A relatively recent publication stated that syringomas were derived from luminal cells of the lowermost intraglandular sweat duct, and poromas tend to differentiate toward the cells of the upper acrosyringium.⁷⁶³ Cylindromas and eccrine spiradenomas have a more complex pattern.²¹⁶ They are now regarded as apocrine tumors.

Although CD44 is strongly expressed in the eccrine coil secretory cells, it has not proved a useful marker of sweat gland differentiation in tumors.⁷⁶⁴ It is expressed not only in syringomas and eccrine poromas but also in tumors of undoubted apocrine origin, such as hidradenoma papilliferum.⁷⁶⁴

Some eccrine tumors contain estrogen receptor protein – a feature of some breast carcinomas.⁷⁶⁵ Myoepithelial cells (as determined by the expression of vimentin and α -smooth muscle actin) are seen in most sweat gland tumors considered to differentiate toward the secretory coil of sweat glands and in most of the traditional apocrine tumors.⁷⁶⁶⁻⁷⁶⁸ The myoepithelioma was considered with the apocrine tumors (see p. 949). Another feature of some sweat gland carcinomas

is the presence of p53 protein; it is rarely present in benign tumors.⁷⁶⁹ The mitotic rate is also an important indicator of malignancy.⁷⁷⁰

It was previously mentioned that some of the tumors traditionally regarded as being of eccrine origin are apocrine in type, whereas the evidence for the histogenesis of a further group of these tumors is still being evaluated.

For purposes of discussion and ease of presentation in this edition, apocrine and eccrine tumors are discussed together and, where possible, grouped according to type of lesion. Thus, nevi and malformations of both are discussed first. Among the benign sweat gland tumors, the poromas, hidradenomas (acrosiomas), and mixed tumors, both apocrine and eccrine, are discussed in adjacent sections. Nevertheless, current information about their lines of differentiation is provided.

Hyperplastic and metaplastic lesions of the eccrine glands are discussed in Chapter 15 (pp. 504–505).

NEVI AND MALFORMATIONS OF SWEAT GLANDS

ECCRINE NEVI AND HAMARTOMAS

The term ‘eccrine hamartomas’ is used to cover the diverse group of nevoid conditions involving the eccrine sweat glands. The simplest lesion is an **eccrine nevus**,⁷⁷¹⁻⁷⁷⁵ a rare abnormality in which there is an increased number of normal-appearing eccrine coils or an increase in the size of the coils (**Fig. 33.41**). A case presenting as a perianal skin tag has been reported.⁷⁷⁶ Sometimes an eccrine nevus produces localized hyperhidrosis.^{777,778} A variant with a conspicuous mucinous stroma has been reported.⁷⁷⁹ In one case, extensive mucinous eccrine nevi were present following the lines of Blaschko.⁷⁸⁰ The eccrine nevus with an angiomyxoid stroma is a related entity.⁷⁸¹ **Eccrine duct hyperplasia** usually occurs as a reactive process (see the discussion of eccrine syringofibroadenomatosis – p. 942), but it has been reported in association with a nasal glioma, a hamartomatous lesion.⁷⁸²

In **eccrine angiomatous hamartoma**,⁷⁸³⁻⁷⁹³ there is an increase in the number of small blood vessels, and sometimes of nerve fibers, mucin, or fat,⁷⁹⁴ in addition to the increase in eccrine glands.⁷⁹⁵ Hair follicles are sometimes associated with this lesion. Overlying verrucous features have been recorded.⁷⁹⁶ In one case, the verrucous features were associated with an underlying hemangiomatous component resembling an angiokeratoma or verrucous hemangioma.^{797,798} In other cases,

Figure 33.41 Eccrine nevus. There is an increase in eccrine glands and ducts. (H&E)

components resembling spindle cell hemangioma or arteriovenous hemangioma were present.^{794,799} Eccrine angiomatous hamartoma can be present at birth or appear in early childhood. Even onset in adulthood has been reported.⁸⁰⁰ Neurofibromatosis type 1 was present in one case.⁸⁰¹ Lesions usually present as a bluish or brown nodule or plaque,⁸⁰² but multiple lesions can occur.⁸⁰³ The extremities are often involved.⁸⁰⁴ Hyperhidrosis and hypertrichosis may be present.⁸⁰⁵ The hyperhidrosis of an eccrine nevus has been successfully treated with botulinum toxin.⁸⁰⁶ Pain and/or tenderness are usually present.⁸⁰⁷ Spontaneous regression has been reported.⁸⁰⁵ GCDPF-15 was present in the eccrine glands in one case.⁸⁰⁸ The lesion reported as a **palmar cutaneous hamartoma** had neurovascular glomic bodies in addition to fat, angiomatous vessels, and eccrine glands.⁸⁰⁹ Wang *et al.* found that in all of their studied lesions, endothelial cells of eccrine angiomatous hamartoma expressed prox1, a lymphatic endothelial nuclear transcription factor, and at least focal D2-40, suggesting that these may be lymphatic proliferations.⁸¹⁰

The **acrosyringal nevus** consists of a proliferation of PAS-positive acrosyringal keratinocytes, which extend down into the dermis as thin anastomosing cords from the undersurface of the epidermis (Fig. 33.42).⁸¹¹ Some of these structures are recognizable as eccrine ducts. Stromal plasma cells may be prominent. Lesions may be linear,⁸¹²

Figure 33.42 (A) Acrosyringal nevus. (H&E) (B) Thin anastomosing cords of cells extend from the undersurface of the epidermis. The cells are PAS positive. (Periodic acid–Schiff)

plaque-like, or multiple.⁸¹¹ Diffuse lesions have been observed in ectodermal dysplasia.⁸¹³ Although usually regarded as an identical lesion,^{814,815} the solitary tumor reported as a syringofibroadenoma⁸¹⁶ does have clinicopathological differences; it is considered with the benign tumors (see p. 942).^{817,818} Incidentally, the term ‘acrosyringal nevus’ was suggested to the author by the late Dr. Hermann Pinkus, who agreed that the lesion had clinical and pathological features that distinguished it from the lesion reported earlier by Mascaro.

The **phakomatous choristoma** is a benign congenital lesion of the eyelid consisting of lens tissue in an ectopic location.⁸¹⁹ It is mentioned here because the irregularly branched ducts and cords, some cystically dilated, can mimic an adnexal tumor. Furthermore, there is no other suitable place for its inclusion. There is a densely fibrotic stroma, psammoma body-like calcifications, and intraluminal degenerated ghost cells. There is strong staining for vimentin and weak focal staining for S100 protein.⁸¹⁹

There are three somewhat related lesions characterized by comedonal dilatation of eccrine ostia, with or without cornoid lamellae. These lesions are comedo nevus of the palm, linear eccrine nevus with comedones, and porokeratotic eccrine ostial nevus. In **comedo nevus of the palm**,⁸²⁰ there are keratotic pits formed by parakeratotic plugs within dilated eccrine ostia. The lesion reported as **linear eccrine nevus with comedones**⁸²¹ resembles nevus comedonicus, with the addition of basaloid nests in the dermis resembling eccrine spiradenoma in some areas and eccrine acrospiroma in others. In **porokeratotic eccrine ostial nevus**, there are cornoid lamellae associated with eccrine ducts.^{822–826} A psoriasiform variant has been described.⁸²⁷

In **eccrine-centered nevus**, there are nevus cells intimately associated with eccrine sweat ducts.^{828,829}

APOCRINE NEVUS

The apocrine nevus is a rare tumor composed of increased numbers of mature apocrine glands extending from the reticular dermis to the subcutis (Fig. 33.43).^{830–833} It has been reported on the upper chest, the temple,⁸³⁴ neck,⁸³⁵ and axilla,⁸³⁶ more often, it is an element of an organoid nevus (nevus sebaceus). It presents as a papule or as a plaque studded with papules.⁸³⁴ Immunohistochemical staining of one case

Figure 33.43 Apocrine nevus. There are collections of mature apocrine glands with decapitation secretion. Dilated ducts are also identified. (H&E)

showed luminal and intercellular canalicular EMA and CEA staining, CK7 and GCDPF-15 staining of secretory cells, and p63 expression of basal secretory and myoepithelial cells.⁸³⁵ The lesion reported as congenital apocrine hamartoma was thought to represent a form of organoid nevus with pure apocrine differentiation on the basis of a deformed follicular structure present in the lesion.⁸³⁷ Apocrine hamartoma has also been used interchangeably with apocrine nevus.⁸³⁴

The cases reported as '*pigmented apocrine hamartoma of the vulva*' were composed of tubules and cysts lined by melanin-containing apocrine cells and also an outer layer of myoepithelial cells.⁸³⁸ The pigmentation appeared to be secondary to colonization of the apocrine glands by dendritic melanocytes.⁸³⁸

ECCRINE HIDROCYSTOMA

Eccrine hidrocystoma is usually solitary, but multiple lesions may occur.⁸³⁹⁻⁸⁴¹ There is a predilection for the periorbital area.⁸⁴² It is discussed further with the other cystic lesions in Chapter 16 (p. 519).

The existence of this entity has been challenged; many, if not all, of these lesions are now regarded as being of apocrine type.^{746,843} However, there are examples of markedly dilated ducts located adjacent to eccrine secretory coils that could be considered retention cysts, if not true eccrine hidrocystomas.

Histopathology

The cysts are unilocular and lined by two layers of cuboidal epithelium. CK7, -8, and -19 were present in some cases. On this basis, they were regarded as being of eccrine origin.⁸⁴⁴

APOCRINE HIDROCYSTOMA (APOCRINE GLAND CYST)

Apocrine hidrocystoma has been regarded by some as an adenomatous cystic proliferation of apocrine glands and by others as a simple retention cyst. For this reason, the term 'apocrine cystadenoma' is sometimes used for these cases. The tumor has a predilection for the head and neck, and it is uncommon in the sites in which apocrine glands are usually found.⁸⁴⁵ Clinically, it may have a bluish color. Apocrine hidrocystoma is considered further with other cutaneous cysts (see p. 519).

In a study of 21 cases of apocrine hidrocystoma and apocrine cystadenoma, it was concluded that cases with true papillary projections containing a fibrous core are proliferative tumors (apocrine cystadenomas) that should be distinguished from apocrine hidrocystomas, which are nonproliferative, cystic lesions.⁸⁴⁶

Histopathology

The cysts are lined by two layers of cells: (1) an inner lining of large columnar cells with eosinophilic cytoplasm often showing luminal decapitation secretion and (2) an outer flattened layer of myoepithelial cells. Papillary projections of epithelium into the lumen are found in approximately one-half of cases. The term '*papillary apocrine gland cyst*' has been used for these cases.⁷⁴⁶ The cytokeratin expression suggests that it is a complex tumor, differentiating into each portion of the apocrine gland.⁸⁴⁷ There is a suggestion from immunohistochemistry that lesions with a proliferative component (apocrine cystadenoma) are different from the pure cystic form.⁸⁴⁸ This was confirmed by the study (discussed previously) that showed that apocrine cystadenomas, in which true papillae were found, had increased Ki-67 staining.⁸⁴⁶

Two cases of an apocrine gland cyst with a hemosiderotic dermatofibroma-like stroma have been reported.⁸⁴⁹

BENIGN SWEAT GLAND TUMORS

SYRINGOMA

Syringomas are usually found as multiple small papules on the lower eyelids and cheeks of adolescent females.⁸⁵⁰ Other variants include solitary and giant⁸⁵¹ lesions; a plaque form,⁸⁵² milia-like lesions,⁸⁵³⁻⁸⁵⁵ tumors limited to the vulva,^{851,856-858} penis,⁸⁵⁹⁻⁸⁶³ axillae and groins,⁸⁶⁴ buttocks,⁸⁶⁵ moustache area,⁸⁶⁶ or scalp,⁸⁶⁷ and acral,⁸⁶⁸ linear,^{869,870} or bathing trunk distributions.⁸⁷¹ Eruptive⁸⁷²⁻⁸⁷⁹ and disseminated forms,⁸⁸⁰ some of which may be familial,⁸⁸¹ have also been described. The case reported as 'linear syringomatous hamartoma' was present at birth.⁸⁸² It was characterized by syringoma-like glands in a desmoplastic stroma. The authors regarded it as a variant of eccrine nevus.⁸⁸² An eccrine nevus has been reported in association with a clear cell syringoma.⁸⁸³ The clear cell variant of syringoma has been associated clinically with diabetes mellitus in many instances.^{884,885} Syringomas appear to be more common in patients with Down syndrome.^{872,886,887} Their occurrence adjacent to a basal cell carcinoma is probably fortuitous.⁸⁸⁸ They are regarded as probable apocrine tumors by Ackerman and colleagues.⁷⁴⁶

In an award-winning poster display at the American Society of Dermatopathology meeting in San Francisco in October 2008, Chandler presented evidence that eruptive syringomas result from autoimmune destruction of dermal eccrine ducts. That study was subsequently published under the title 'Autoimmune Acrosyringitis with Ductal Cysts'.⁸⁸⁹ Eruptive syringomas have also developed in an area of skin subject to waxing.⁸⁹⁰ The lesions were thought to have resulted from reactive inflammation in the dermis.⁸⁹⁰

Because syringomas are benign and usually asymptomatic, treatment is usually offered for cosmetic reasons. Treatment options include surgical excision, dermabrasion, cryotherapy, electrodesiccation with curettage, and CO₂ laser, with or without trichloroacetic acid.⁸⁹¹ Topical retinoids have also been used. Oral tranilast, an anthranilic acid derivative, has been used with some success to treat multiple syringomas.⁸⁵⁷

Histopathology⁸⁵⁰

Syringomas are dermal tumors composed of multiple small ducts lined usually by two layers of cuboidal epithelium (Fig. 33.44). Sometimes, the ducts have a comma-like tail resembling those seen in desmoplastic trichoepithelioma. Solid nests and strands of cells, sometimes having a basaloid appearance, may be present. Some ducts are dilated and contain eosinophilic material. There is usually a dense fibrous stroma.

In the clear cell variant, the ducts are lined by larger epithelial cells with pale or clear cytoplasm (Fig. 33.45).^{884,892} This clear cell change may involve only part of the tumor or be limited to the cells adjacent to the duct lumina. The clear cells contain abundant glycogen. It is regarded as a 'metabolic' variant of the conventional syringoma.⁸⁹³

Rare variants include the presence of numerous mast cells in the stroma⁸⁹⁴ or of nevus cells, including Spitz nevus cells, admixed with the syringomatous elements.^{850,895,896} Syringoma-like sweat duct proliferation is found as an incidental finding in scalp biopsies taken for the histological evaluation of alopecia.^{897,898} It has also been found in prurigo nodularis.⁸⁹⁹ Malignant degeneration is very rare, and the tumors designated as malignant syringoma (syringoid eccrine carcinoma) are probably malignant *ab initio*. Syringomas differ from microcystic adnexal carcinoma by their lack of deep extension and of perineural infiltration.^{852,900} They are easily distinguished from the exceedingly rare change known as sclerosing adenosis of sweat ducts.^{745,901}

Staining with monoclonal anti-eccrine gland antibodies has shown positivity for EKH-6 (eccrine secretory and ductal structures), but the tumor cells are negative for EKH-5 and SKH1, which label eccrine

Figure 33.44 (A) Syringoma. (B) Multiple small ductal structures, lined by two layers of cuboidal epithelium, are present in a fibrous stroma. (H&E)

Figure 33.45 Syringoma (clear cell variant). The ductal structures are lined by epithelium having pale cytoplasm. (H&E)

secretory elements.^{756,902} The cytokeratin pattern has been further characterized: the cells express CK1/5/10/11/19 and also CK14 variably.^{893,903} Syringomas usually contain CEA, whereas desmoplastic trichoepitheliomas do not.²²¹ Ferritin is present in the outermost layer of cells in the epithelial elements of the syringoma, in a similar pattern to that seen in normal eccrine ducts.⁷⁵⁷ Progesterone receptors are expressed in most syringomas, supporting the view that they are under hormonal control.^{904,905} In one series, they were not expressed in all 15 cases on the vulva.⁸⁹¹

Electron microscopy

There are numerous microvilli on the cells bordering the lumina and a band of periluminal tonofilaments.^{902,906} Intracytoplasmic lumen formation and keratohyaline granules in luminal cells have also been reported.⁹⁰⁶

Differential diagnosis

A small superficial biopsy of a syringoma can display features resembling microcystic adnexal carcinoma and sometimes desmoplastic trichoepithelioma. Each of these can have small keratin cysts resembling milia. A lack of ductal differentiation excludes desmoplastic trichoepithelioma. However, a deeper biopsy, sufficient to show changes in the subcutis, is the preferred method to exclude microcystic adnexal carcinoma because the latter is not well demarcated, shows permeative growth into the subcutis, and is likely to display perineural infiltration.

CYLINDROMA

Cylindromas are usually found as small solitary lesions on the head and neck. There is a strong predilection for middle-aged and elderly females. Large variants, usually with multiple coalescing tumors (turban tumors), may arise on the scalp and forehead. A rare variant with multiple lesions in linear array has been reported.⁹⁰⁷ Multiple cylindromas occur in familial cylindromatosis (OMIM 132700) and the Brooke–Spiegler syndrome (OMIM 605041) in which multiple trichoepitheliomas are associated with multiple cylindromas, and sometimes spiradenoma or spiradenoma/cylindroma overlap lesions.^{171–173,908–914} It is autosomal dominant in inheritance.⁹¹⁵ This association is compelling evidence for the folliculosebaceous–apocrine origin of these various tumors. They are different phenotypic expressions of mutations in the same gene, the *CYLD* gene on chromosome 16q12–q13 (see p. 911).^{916,917} Multiple cylindromas without the other components of the Brooke–Spiegler syndrome appear to be exceedingly rare, if they occur at all.⁹¹⁸ Cylindromas have been reported in association with monomorphic adenomas of the parotid gland.⁹¹⁹ Recently, fusion of the two transcription factor genes *MYB* and *NFIB*, a feature of adenoid cystic carcinomas of the breast and head and neck, was also found in sporadic cylindromas, suggesting a genetic link between these tumors.⁹²⁰

Locally aggressive behavior and malignant transformation are uncommon and usually associated with long-standing turban tumors of the scalp.^{921–924} However, metastasis of malignant tumors is very rare.⁹²⁵

The origin of this tumor has been controversial: some immunohistochemical studies suggest that cylindroma is linked to the secretory coil of the apocrine gland rather than the coiled duct region of the eccrine gland, as originally thought.^{926–928} A more recent study using the monoclonal antibody IKH-4, which is believed to be eccrine specific, showed positive staining, again putting the histogenesis of cylindroma into dispute.⁷⁴⁹ However, its recent association with mutations in the *CYLD* gene, which may also occur in familial trichoepitheliomas, seems to implicate the folliculosebaceous–apocrine unit.

Histopathology

Cylindromas are poorly circumscribed dermal tumors composed of irregularly shaped islands and cords of basaloid cells surrounded by conspicuous eosinophilic hyaline bands that are PAS positive and diastase resistant (Fig. 33.46). Droplets of similar hyaline material may be present in the cell nests. The hyaline basement membrane contains type IV and type VII collagen.^{929,930} There is usually a thin band of uninvolved connective tissue beneath the epidermis; however, the large turban tumors will ulcerate. Subcutaneous extension may also occur.

Most of the tumor islands have two cell types: (1) a peripheral cell with a dark-staining nucleus and a tendency for palisading and (2) a larger cell with a vesicular nucleus more centrally located. Small duct-like structures are sometimes present.

The stroma is composed of loosely arranged collagen containing an increased number of fibroblasts. A more compact stroma is occasionally present. Stromal ossification is a rare phenomenon.⁹³¹

Areas resembling spiradenoma (see later) will sometimes be present, and there may also be tumor lobules with overlap features between these two entities.^{913,932,933} A patient with the Brooke–Spiegler syndrome had a tumor with features of cylindroma, spiradenoma, and trichoepithelioma in the same lesion.¹⁷⁴ In another patient with this syndrome, hybrid lesions containing two or more of these already mentioned components and/or trichoblastomatous, lymphadenomatous, and sebaceous features were present.⁹³⁴

Aggressive or malignant behavior is characterized by loss of the hyaline sheath and expanded cellular islands composed predominantly of larger cells, devoid of peripheral palisading.⁹²⁴ In a study of 15 malignant neoplasms arising from cylindroma, spiradenoma, or spiradenocylindroma and 12 benign control lesions, immunostaining for p53 was seen at least to some degree in most of the malignant lesions but was weak and focally positive in only 3 of 12 of the benign lesions. However, the value of p53 staining in differentiating these benign and malignant tumors is questionable because staining is heterogeneous, and some unquestionably malignant foci show a lack of p53 staining.⁹³⁵ Only one malignant lesion, and none of the lesions in the benign group, showed a *TP53* mutation; interestingly, however, single nucleotide polymorphisms were detected in all malignant lesions, and identical polymorphisms were found in all of the benign lesions.⁹³⁵

Although the expression of cytokeratins could be interpreted as indicating an eccrine origin, the presence of lysozyme, human milk factor globulin 1, α -smooth muscle actin, and α_1 -antichymotrypsin favors an apocrine origin. CEA and EMA are also expressed.⁹²⁷ Both cylindroma and spiradenoma express CK7, -8, and -18.⁹³³ In a comparative study of cylindroma of the skin and of the breast, both tumors did not express CK20, GCDPF-15, or estrogen or progesterone receptor.⁹³⁶ Both tumors expressed CK7 in the central basaloid cells, whereas ducts were highlighted by EMA and CEA.⁹³⁶

Dermoscopy shows a pink background with arborizing telangiectasia, blue dots/globules, and sometimes ulceration. Basal cell carcinoma shows similar findings, except that the globules are gray in basal cell carcinomas.^{937,938}

Electron microscopy^{906,939}

Electron microscopy shows small dense basal cells, large light indeterminate cells, ductal cells, secretory cells containing secretory granules, and some Langerhans cells. Ductal structures are also present. The thick hyaline band is composed of thickened amorphous basal lamina and a fibrous component consisting of anchoring fibrils.⁹⁰⁶ Collagen fibrils of varying width are also present.

Differential diagnosis

Occasionally, the configuration of cylindroma can be mimicked by basal cell carcinoma. However, that tumor lacks the closely applied

Figure 33.46 (A) Cylindroma. (B) The basaloid cells are arranged in irregularly shaped islands surrounded by a thin band of hyaline material. (H&E)

hyaline basement membrane or hyaline droplets and instead shows a fibromucinous stroma with clefting artifact. Perhaps the tumor most closely resembling cylindroma is the spiradenoma; in fact, as noted, these tumors can occur together, either in the same lesion or as separate lesions, and as components of the Brooke–Spiegler syndrome.⁹¹⁰ Spiradenoma tends to consist of larger basophilic nodules, contains duct-like structures with two cell types (cells with hyperchromatic nuclei and other, larger cells with pale nuclei; two cell types can also be identified in cylindroma, although in a slightly different arrangement), and are associated with an edematous stroma with dilated vessels. Nevertheless, the occasional association with cylindroma and overlapping histopathologic features suggest a close relationship between these two lesions.

SPIRADENOMA

Spiradenoma is usually a solitary gray-pink nodule, less than 1 cm in diameter, arising on the head and neck, trunk, or, less commonly, the extremities of adults.⁹⁴⁰ Satellite tumors, multiple lesions,^{850,941–943} giant variants,⁹⁴⁴ a linear^{945–947} or zosteriform^{948,949} distribution, and occurrence at birth⁹⁵⁰ and in infancy⁹⁵¹ have also been described. It may arise in an organoid nevus.⁹⁵² Pain and/or tenderness are frequently present, but one study suggested that these features may have been overstressed in the past.⁹⁴⁰

Spiradenoma has been associated with cylindromas in the same patient (discussed previously),^{912,942,953} and tumors with overlap features between these two types have also been described.⁹¹³ Many of these cases have the Brooke–Spiegler syndrome (see p. 911). Ackerman and colleagues regard both tumors as apocrine in type. Malignant transformation is a very rare event.^{913,924,940,954–958} It has been reported in spiradenomas associated with the Brooke–Spiegler syndrome.⁹⁵⁹ It appears to be accompanied by increased expression of p53 protein,⁹⁶⁰ but see the study discussed under Cylindroma.⁹³⁵ Among a variety of adnexal tumors, intense nuclear immunoreactivity for β -catenin has been found in spiradenomas (as well as pilomatricomas), and two proteins, axin and GSK-3 β , that induce the degradation of β -catenin are down-regulated in spiradenoma. This downregulation may represent an important signaling alteration in the development of this tumor.⁹⁶¹

Histopathology^{940,962}

The tumor is composed of one or more large, sharply delineated basophilic nodules in the dermis, unattached to the epidermis and sometimes extending into the subcutis. Small satellite lobules may be present. The tumor nodules are composed of aggregates of cells in sheets, cords, or islands or with a trabecular arrangement (Fig. 33.47). Two cell types are present: small dark basaloid cells with hyperchromatic nuclei and a more frequent larger cell with a pale nucleus that tends to be near the center of the clusters. The cells are PAS negative, but droplets of PAS-positive hyalin may be present in some areas of the tumor. A few duct-like structures are often present (Fig. 33.48). Other findings include squamous eddies, small cysts, and lymphocytes infiltrating the tumor nests. Irregular, thin bands of fibrous tissue containing blood vessels are present within the tumor lobules. Perivascular spaces, containing some lymphocytes, sometimes form between the blood vessels and the tumor cells.⁹⁶³ The stroma between lobules may be edematous, and sometimes there are prominent vessels with telangiectasia and even hemorrhage.^{944,964} Dilated vessels rimmed by sclerosis have been called ‘ancient’ changes.⁹⁶⁵ Cylindromatous areas are sometimes present.^{912,932,933} Adenomatous elements have also been described,⁹⁶⁶ and a recent case has been reported to have adenomyoepitheliomatous changes, resembling the adenomyoepitheliomas of other organs such as the breast.⁹⁶⁷

The strands of cells are cytokeratin positive and the lumina are CEA positive.⁹⁴⁴ The pattern of cytokeratin expression mirrors that seen in

Figure 33.47 Spiradenoma. This large lesion is partly cystic and hemorrhagic. (H&E)

the transitional portion between the secretory segments and the coiled ducts of sweat glands.⁹⁶⁸ In another report, there was coexpression of CK17 and SMA, suggesting myoepithelial differentiation in this case.⁹⁶⁹ Abundant T lymphocytes and Langerhans cells are found within the tumor lobules.⁹⁷⁰

Dermoscopy of a spiradenoma has shown branching vessels and blue and orange clods; the blue clods correspond to hemorrhagic areas.⁹⁷¹

Electron microscopy

There is some variability in the ultrastructural findings.^{944,962,972} The tumor is composed of sheets of cells separated into lobules by strands of amorphous and fibrillar material.⁹⁶² The most common cell is a clear polygonal or round cell with mitochondria, small vesicles, and sometimes glycogen in the cytoplasm.⁹⁴⁴ A rare dark cell is present. Although lumina have not always been seen,⁹⁶² they have been reported, with microvilli on the lining cells. Intracytoplasmic lumina have also been seen within the epithelial cells.⁹⁷²

POROMA GROUP

The subclassification of the poroma group and the hidradenomas is a confusing area of dermatopathology. An overlap in histological features occurs not only between the various entities within each of these two groups but also between the two. For example, it is not uncommon for a tumor to resemble poroma superficially and to have a deeper

Figure 33.48 Spiradenoma. (A) The tumor lobule has a thin fibrous capsule. There are small basaloid cells admixed with some larger cells. (B) Small duct-like structures are present within a tumor lobule. (H&E) (C) Another case with an inset showing an infiltrate of CD3⁺ lymphocytes in the tumor nests. (H&E and immunoperoxidase inset)

dermal component of solid-cystic hidradenoma. Some authors have used the terms 'solid-cystic hidradenoma' and 'acrospiroma' to encompass both the poroma and the hidradenoma group, whereas others have used the terms for an individual tumor in the hidradenoma group.⁹⁷³ The term 'poroid hidradenoma' has been applied to a dermal tumor with solid and cystic components resembling the hidradenoma but composed of poroid-type cells.^{746,974} It is regarded as the eccrine equivalent of apocrine hidradenoma (see later). It has been reported in association with a pigmented eccrine poroma.⁹⁷⁵

Here, the poroma group is subdivided into eccrine poroma, dermal duct tumor (dermal eccrine poroma), hidroacanthoma simplex (intraepidermal poroma), syringoacanthoma, and syringofibroadenoma. Lesions have been described that contained two or three histologically distinct components: hidroacanthoma simplex, eccrine poroma, and dermal duct tumor.^{976,977}

Ackerman believes that some poromas are of apocrine origin, but they can only be inferred to be apocrine on the basis of a connection of one or more elongated tubules to infundibula.⁷⁴⁶

Apocrine poroma

Undoubted examples of a poroid neoplasm with apocrine features occur.⁹⁷⁸ Often, there is follicular and/or sebaceous differentiation as well, reflecting the common origin of the folliculosebaceous-apocrine unit.^{979,980} Such tumors could also be regarded as complex adnexal tumors, examples of which have been reported in the past as poroma-like adnexal adenoma and sebocrine adenoma (see p. 953). Apocrine poromas appear to originate from follicular infundibula.

Histopathology

Anastomosing lobules of small uniform basaloid cells form small ductal structures lined by eosinophilic cuticles.⁹⁷⁸ Focal hair follicle and/or sebaceous differentiation are common.⁹⁸¹ In one case, follicular differentiation was a major feature of the lesion.⁹⁸² One case resembled hidroacanthoma simplex with underlying sebaceous glands.⁶⁹⁷ Similar cases were regarded by Steffen and Ackerman as seborrheic keratoses with sebaceous differentiation.⁵⁴⁹

Cytokeratin expression has not assisted in the differentiation of apocrine and eccrine poromas.⁹⁸³

Eccrine poroma

Eccrine poroma, a tumor derived from the acrosyringium, presents as a solitary, pink or red exophytic nodule, usually on plantar or palmar skin.^{977,984,985} It may also be found elsewhere on the lower extremities and hands and, occasionally, on any other area of the body with sweat glands.⁹⁸⁶ Pigmented poromas have a predilection for non-acral sites.⁹⁸⁷ It has also arisen on a burn site.⁹⁸⁸ Some of the lesions on the head and neck may be of apocrine origin.⁹⁸⁹ It usually arises in middle-aged or elderly people. Rare cases have been reported in childhood,⁹⁹⁰ including one congenital case.⁹⁹¹ A rapidly growing eccrine poroma of the nose has been reported in a pregnant woman.⁹⁹² Multiple lesions (eccrine poromatosis) are very rare, and some purported cases appear to be examples of acrosyringial nevus.^{811,993} Origin in an area of chronic radiation dermatitis has been documented.⁹⁹⁴⁻⁹⁹⁶ In another patient, multiple poromas arose in the setting of total body irradiation and immunosuppression with allogeneic bone marrow transplantation for the treatment of acute lymphocytic leukemia.⁹⁹⁷

Histopathology⁹⁹⁸

Eccrine poroma is a circumscribed tumor composed of cords and broad columns of uniform basaloid cells extending into the dermis from the undersurface of the epidermis (Fig. 33.49). The cells are smaller than, and well delineated from, the epidermal cells with which they are in

Figure 33.49 Poroma. (A) Broad, anastomosing bands composed of small cuboidal cells show multiple connections to the overlying epidermis. (H&E) (B) Cords of basaloid cells extend into the dermis. (H&E)

contact. They are PAS positive, and much of the PAS-positive material is diastase sensitive. Melanin pigment is sometimes present and is sometimes visible clinically.^{999,1000} Several mechanisms have been proposed for the melanocyte colonization of various appendageal tumors.^{987,1001–1003} Increased endothelin-1 expression is one of these proposed mechanisms.¹⁰⁰⁴ Ducts and, less commonly, small cysts may also be seen within the tumor columns. The stroma is usually richly vascular with some telangiectatic vessels, contributing to the clinical appearance.

Uncommonly, divergent adnexal differentiation is seen in eccrine poromas, with focal sebaceous,¹⁰⁰⁵ pilar, and possibly apocrine secretory differentiation.¹⁰⁰⁶ On the basis of the common embryological origin of follicular, sebaceous, and apocrine structures, it has been suggested that some 'eccrine' poromas might be of apocrine origin (discussed previously).^{989,1006} CK1 and -10 are expressed in the tumor nests.¹⁰⁰⁷

Electron microscopy

The tumor cells have numerous connecting desmosomes, cytoplasmic tonofilaments, glycogen granules, and intracytoplasmic lumina. The latter appear to coalesce to form larger intercellular duct-like structures resembling embryonic intraepidermal sweat ducts.¹⁰⁰⁸

Differential diagnosis

The most important differential consideration is porocarcinoma. Although portions of porocarcinomas may bear a close resemblance to their benign counterparts, true porocarcinomas show infiltrative growth and areas of spontaneous necrosis. Some poromas show focal nuclear enlargement or prominent nucleoli, sometimes with limited mitotic activity.¹⁰⁰⁹ Nevertheless, as a general rule, if the overall configuration is that of a conventional poroma, a diagnosis of malignancy should not be rendered.

Dermal duct tumor

The term 'dermal duct tumor' was coined by Winkelmann and McLeod in 1966 for a tumor composed of basaloid cells, like an eccrine poroma, but located in the dermis.¹⁰¹⁰ Relatively few cases have been reported since, and this may simply reflect the hesitation of some dermatopathologists to make the diagnosis, particularly when multiple sections through a presumed dermal duct tumor often show a connection with the undersurface of the epidermis or areas resembling solid-cystic hidradenoma (poroid hidradenoma). Clinically, dermal duct tumor presents as a firm papule, plaque, or nodule, particularly on the lower limbs or head and neck region.¹⁰¹¹ They measure from a few millimeters to several centimeters in diameter.¹⁰¹²

Histopathology

The tumor is composed of islands of basaloid tumor cells within the dermis. Duct-like structures are prominent in many of the nests (Fig. 33.50), and the tumor may itself connect with a normal-appearing eccrine duct. An epidermal connection is often found if multiple sections are examined.¹⁰¹³ The cells are PAS positive, but this is usually not as striking as in eccrine poroma. Melanin pigment is sometimes present.

In the clear cell variant, there are multiple solid aggregations of clear cells involving the dermis. Ductal structures are also present.¹⁰¹² The neoplastic cells are immunoreactive for MNF116 and AE1/AE3 cytokeratins but not for CAM5.2 or CK7.¹⁰¹² EMA, CEA, and GCDPF-15 decorate the ductal structures but not the neoplastic cells.¹⁰¹²

Electron microscopy

The tumor is composed of clear, dark, and luminal cells, with the clear cell being predominant.¹⁰¹¹ There are microvilli on the luminal side of the cells lining the ducts within the cell nests.

Figure 33.50 Dermal duct tumor. Intradermal islands of basaloid cells are present. Some duct-like structures can be identified. (H&E)

Hydroacanthoma simplex

Hydroacanthoma simplex (intraepidermal eccrine poroma) is a solitary plaque or nodular lesion found particularly on the extremities and the trunk.^{1014–1016} It arises throughout adult life, and there is an equal sex incidence. Clinically, it resembles a seborrheic keratosis or basal cell carcinoma. Many of the cases reported in the literature as hydroacanthoma simplex are probably examples of the clonal variant of seborrheic keratosis;¹⁰¹⁷ two cases purporting to be hydroacanthoma simplex with porocarcinomatous transformation^{1018,1019} are possibly other entities.¹⁰²⁰ A pigmented malignant hydroacanthoma simplex arising in a benign variant has been reported. Although mimicking seborrheic keratosis, the lesion was thought to be a distinctive entity.¹⁰²¹ Such tumors are best called porocarcinoma *in situ*.^{1022,1023}

Histopathology

Hydroacanthoma simplex is composed of well-circumscribed nests of cuboidal to oval basaloid cells within the epidermis, resembling those seen in eccrine poroma (Fig. 33.51). The cells are smaller than neighboring epidermal keratinocytes, and they contain some glycogen. Rarely, melanin pigment is present.¹⁰²⁴ Reports that mention squamous and spindle cell variants¹⁰¹⁵ probably included seborrheic keratoses.¹⁰²⁰

A few ductal structures may sometimes be seen within the islands. The epidermis is usually acanthotic with some overlying hyperkeratosis. A dermal component resembling solid-cystic hidradenoma is sometimes present.

One immunohistochemical study showed that the tumor cells stain intensely with antikeratin antibodies (using an AE1/AE3 cytokeratin ‘cocktail’) but not with CEA, which did stain adjacent normal acrosyringium.¹⁰²⁵ On the basis of these findings and electron microscopy (see later), the authors concluded that the case studied ‘did not appear to arise from or differentiate toward the luminal cells of the acrosyringium’.¹⁰²⁵ Hydroacanthoma simplex may arise from the *outer* cells of the intraepidermal eccrine duct. In another immunohistochemical study of hydroacanthoma simplex, the tumor cells expressed CK14 and CK17. There was an absence of CK1, CK5, and CK8.¹⁰²⁶

The reported case of malignant hydroacanthoma simplex was composed of an intraepidermal proliferation of atypical polygonal poroid cells forming large, sharply demarcated nests with colonization of

Figure 33.51 Hydroacanthoma simplex. Well-circumscribed nests of basaloid cells are present within the epidermis. (H&E)

dendritic melanocytes.¹⁰²¹ The intracytoplasmic lumina of the ductal structures expressed both EMA and CEA.¹⁰²¹

Electron microscopy

The tumor cells contain few desmosomes, decreased numbers of tonofilaments, and abundant cytoplasmic glycogen.¹⁰²⁵

Differential diagnosis

Seborrheic keratoses of the clonal type may have islands of cells within the epidermis, the so-called ‘Jadassohn phenomenon’. However, the cells in seborrheic keratoses are not as small and basaloid and do not contain glycogen. Both clonal seborrheic keratoses and hydroacanthoma simplex have a similar expression of cytokeratin, although there are more Langerhans cells in clonal seborrheic keratoses than in hydroacanthoma simplex.¹⁰²⁷ EMA positivity helps to distinguish hydroacanthoma simplex from seborrheic keratosis and basal cell carcinoma, which are EMA negative. Poroid cells are also positive for CK10.¹⁰²⁸ Another means of distinguishing clonal seborrheic keratosis from hydroacanthoma simplex is through immunostaining for lumican, which is a member of the small leucine-rich proteoglycan family that has a role in the assembly of collagen fibers in extracellular matrices. Lumican is positive in the poroid cells of intraepidermal sweat ducts and is found in the intraepidermal nests of hydroacanthoma simplex in almost 80% of cases, whereas the cells in clonal seborrheic keratosis are lumican negative in most cases.¹⁰²⁹ Another tumor that shows the Jadassohn phenomenon of intraepidermal nesting is the so-called ‘intraepidermal epithelioma of Jadassohn’.¹⁰³⁰ This is perhaps the most controversial entity in dermatopathology.¹⁰³¹ It is assumed to be derived from acrosyringial keratinocytes (as are hydroacanthoma simplex, acrosyringial nevus, and syringofibroadenoma). Many believe that this entity is heterogeneous and includes seborrheic keratoses with atypia or Bowenoid transformation and also variants of intraepidermal carcinoma.^{1020,1032} It has not been mentioned in the recent literature.

Syringoacanthoma

Syringoacanthoma was described by Rahbari in 1984 as a tumor derived from the acrosyringium.¹⁰³³ It is said to differ from hydroacanthoma simplex by the presence of prominent acanthosis and papillomatosis and by less orderly intraepidermal nests. Steffen and Ackerman believe that it is not a distinct entity.¹⁰²⁰

SYRINGOFIBROADENOMA

It has been suggested⁸¹⁴ that eccrine syringofibroadenoma, as described by Mascaro in 1963,⁸¹⁶ is identical to the acrosyringial nevus of Weedon and Lewis⁸¹¹ (see the discussion of eccrine hamartomas, p. 933), but there do appear to be some clinicopathological differences.⁸²³ The eccrine syringofibroadenoma presents as a solitary, often large, hyperkeratotic nodular lesion with a predilection for the extremities.^{814,817,1034,1035} Rare sites of involvement include the nail apparatus¹⁰³⁶ and an organoid nevus.¹⁰³⁷ This term has also been applied to diffuse, zosteriform, and multiple lesions resembling the case reported as an acrosyringial nevus.¹⁰³⁸ One such case produced diffuse plantar hyperkeratosis. It may have been the result of a postsomatic mutation in the early embryonic stage.¹⁰³⁹ The terms ‘acrosyringial adenomatosis’ and ‘eccrine syringofibroadenomatosis (Mascaro)’ have been suggested as appropriate designations for the more diffuse cases.^{2,1040–1042} Eccrine syringofibroadenomatosis can occur in association with hidrotic ectodermal dysplasia.^{1043,1044} It has been said that the lesions are somewhat different in the two variants, Clouston’s syndrome and the Schöpf syndrome. HPV-10 has been detected in the lesions occurring in Clouston’s syndrome.¹⁰⁴⁵ Eccrine syringofibroadenomatosis has also been reported in a familial setting in association with ophthalmological abnormalities.¹⁰⁴⁶

The occurrence of this phenomenon next to inflammatory dermatoses and tumors, often in an acral location, has been called *reactive eccrine syringofibroadenomatosis*. Because stromal changes are minimal in some instances, ‘eccrine duct hyperplasia’ would be a better term. This reactive change has been seen next to palmoplantar erosive lichen planus,¹⁰⁴⁷ bullous pemphigoid,¹⁰⁴⁸ a burn scar,¹⁰⁴⁹ pincer nail,¹⁰⁵⁰ an ileostomy stoma,^{1051,1052} squamous cell carcinoma,^{1053–1055} and a chronic diabetic foot ulcer.¹⁰⁵⁶ It has also occurred as multiple lesions on the foot in a patient with previous lepromatous leprosy.¹⁰⁵⁷

It may present as a ‘mossy’ leg, resembling lymphedematous keratoderma.¹⁰⁵⁸ A polyp of the uterine cervix with eccrine syringofibroadenoma features has also been reported.¹⁰⁵⁹ The various subtypes of this condition are listed in Table 33.1.

Histopathology^{814,817,1060}

There are thin anastomosing epithelial cords and strands forming a lattice and connected to the undersurface of the epidermis (Fig. 33.52). The cells are smaller and more basophilic than the epidermal keratinocytes. Nests of clear cells have been reported.^{1061–1063} Ducts are present within the tumor. Between the strands, there is a rich fibrovascular stroma. The tumor does not have the strong PAS positivity or the abundant stromal plasma cells noted in the case reported as an acrosyringial nevus.⁸¹¹ However, plasma cells have not been a feature in many of the other multiple/diffuse cases. In one of the reactive peristomal cases, there was the formation of hybrid epidermal–colonic mucosa glandular structures, intraepidermal areas of sebaceous differentiation, and the induction of hair

follicles.¹⁰⁵² Syringofibroadenoma change has also occurred in clear cell acanthoma and was found in 19% of 47 cases of clear cell acanthoma in one study.¹⁰⁶⁴

The term ‘**syringofibrocarcinoma**’ has been suggested for a single case in which a net-like arrangement of cytologically malignant cells showing ductal differentiation impinged on a benign component.¹⁰⁶⁵ Subsequently, other cases have been reported in which carcinomatous transformation of syringofibroadenoma was thought to have occurred rather than the development of this entity as a reactive phenomenon in a pre-existing carcinoma.^{1066,1067} One of the patients had ectodermal dysplasia.¹⁰⁶⁷

Immunohistochemical studies have not shown consistent results with respect to cytokeratin expression, but they seem to indicate differentiation toward the acrosyringium and dermal duct.^{1034,1068–1072} Expression of CK19 is regarded as indicating ductal differentiation, whereas the presence of CK1, involucrin, and filaggrin represents acrosyringial differentiation.¹⁰⁶³ One clear cell variant expressed GCDPF-15 but not estrogen or progesterone receptors.¹⁰⁶³

Electron microscopy

Intracellular duct formation, characteristic of developing acrosyringia, has been observed. Abundant glycogen is also present.^{1068,1073}

PAPILLARY ECCRINE ADENOMA

The benign papillary eccrine adenoma was first described by Rulon and Helwig in 1977.¹⁰⁷⁴ It presents as a slowly growing firm nodule with a predilection for the extremities of black people.^{1074–1081} Ackerman and colleagues include this group with their tubular adenomas of apocrine origin.⁷⁴⁶

Histopathology^{1074,1075}

Papillary eccrine adenoma is a circumscribed dermal tumor composed of multiple variably dilated duct-like structures lined by two or more layers of cells.¹⁰⁷⁶ The inner layer often forms intraluminal papillations of variable complexity (Fig. 33.53).¹⁰⁷⁵ This latter feature is not always prominent in all areas of the tumor. There is no decapitation secretion. The epithelial cells may show focal clear cell change and even focal squamous differentiation. Some of the lumina contain an amorphous eosinophilic material.¹⁰⁸¹ Immunoperoxidase studies have demonstrated the presence of CEA, cytokeratins (particularly CK8 and CK14), and S100 protein.^{1076,1078,1079,1082,1083} The unique pattern of some cases, which are devoid of apocrine features, together with the positive staining with the eccrine-specific antibody IKH-4 are reasons for the retention of an eccrine variant of tubular adenoma. It is acknowledged

Figure 33.52 Syringofibroadenoma. A lattice of thin epithelial cords is connected to the undersurface of the epidermis. The cells are smaller and more basaloid than the overlying epidermal keratinocytes. (H&E)

Table 33.1 Subtypes of eccrine syringofibroadenoma (ESFA)
• Solitary ESFA
• Multiple (diffuse, zosteriform, linear) ESFA (eccrine syringofibroadenomatosis)
• Multiple ESFA with hidrotic ectodermal dysplasia
• Familial ESFA with ophthalmological abnormalities
• Reactive ESFA (reactive eccrine syringofibroadenomatosis) associated with inflammatory or neoplastic disorders, including lichen planus, bullous pemphigoid, burn scar, pincer nail, ileostomy stoma, diabetic foot ulcer, leprosy, mossy foot, and squamous cell carcinoma

Figure 33.53 Papillary eccrine adenoma. (A) Within the dermis, there are numerous duct-like structures. (B) A few intraluminal papillations arise from the wall of the duct-like structures in the dermis. (H&E)

that apocrine variants are far more common. The stromal connective tissue may show hyalinized collagen and a focal increase in fibroblasts. Inflammatory cells are usually sparse.

Electron microscopy

The duct-like structures are composed of basal and luminal cells, with the latter containing intracytoplasmic cavities but not secretory granules.

HIDRADENOMA (ACROSPIROMA)

Considerable confusion exists in the literature concerning the most appropriate designation for this tumor. Wilson Jones called it a 'nosological jungle'.¹⁰⁸⁴ Terms used have included 'solid-cystic hidradenoma',¹⁰⁸⁵ 'eccrine acrospiroma',⁹⁷³ 'clear cell hidradenoma',¹⁰⁸⁶ 'eccrine sweat gland adenoma',¹⁰⁸⁷ and 'clear cell myoepithelioma'.¹⁰⁸⁸ This topic is further confused by the separation of apocrine hidradenomas from a less common eccrine group, which has also been called poroid hidradenoma. The apocrine group (apocrine hidradenoma) is composed

of clear, polygonal, and mucinous cells, whereas the eccrine lesion (hidradenoma, poroid hidradenoma) consists of poroid and cuticular cells.^{1089,1090}

Apocrine hidradenoma

Most of the cases reported previously as eccrine hidradenoma and eccrine acrospiroma have been reclassified as apocrine hidradenoma on the basis of their presumed apocrine histogenesis. The terms 'nodular hidradenoma' and 'clear cell hidradenoma' are also used.^{1091,1092} They usually present as solitary nodules 2 or 3 cm in diameter, but larger variants occur. They predominate in females. There is no site predilection. They can occur at all ages, including infancy.^{1093,1094} Local recurrence can occur, particularly if the lesion is incompletely excised. The malignant variant, hidradenocarcinoma, is exceedingly rare (see p. 955). It may arise *ab initio* or by transformation of a benign lesion.

A skin-type hidradenoma associated with a t(11;19) translocation has been reported in the breast parenchyma.¹⁰⁹⁵ An identical translocation has also been reported in a cutaneous (clear cell) hidradenoma.¹⁰⁹⁶ The fusion genes are the mucoepidermoid carcinoma-translocated 1 (MECT1) gene on chromosome 19p13 and the mastermind-like family (MAML2) gene on chromosome 11q21.¹⁰⁹⁶

Histopathology^{1096,1097}

Hidradenomas are usually circumscribed non-encapsulated multilobular tumors, centered on the dermis but sometimes extending into the subcutis. Epidermal connections are present in up to one-fourth of cases.¹⁰⁸⁵ Mucinous syringometaplasia has been described in one case, overlying a clear cell variant of hidradenoma.¹⁰⁹⁸ Hidradenomas may be solid or cystic in varying proportions. Uncommonly, they are pedunculated. Sometimes, large cystic spaces are present and may contain sialomucin attached to the surface of the lining cells. The closely arranged tumor cells, which may be round, fusiform, or polygonal in shape, are biphasic in cytoplasmic architecture, with one type having clear and the other eosinophilic cytoplasm (Fig. 33.54). There are variable proportions of each cell type in different tumors, but clear cells predominate in less than one-third.^{1085,1093} Sometimes, only a few clear cells can be seen. They contain glycogen and some PAS-positive diastase-resistant material but no lipid. The nuclei of the clear cells tend to be smaller than those in the eosinophilic cells. The nuclei of the nonclear cells are often elongated, and approximately one-third of these cells often contain nuclear grooves.¹⁰⁹¹ Focal goblet-cell metaplasia is sometimes seen.¹⁰⁹⁹ A diffuse proliferation of mucinous epithelium (mucinous hidradenoma) is rare.¹¹⁰⁰ Mitoses are variable in number; their presence does not necessarily indicate malignancy.¹¹⁰¹ However, in one study, mitoses and atypical nuclear changes were associated with an increased local recurrence rate and even subsequent malignant transformation.¹¹⁰² Other cellular variations include an oncocytic variant,¹¹⁰³ an epidermoid variant^{1104–1106} with large polyhedral cells having a squamous appearance, and a pigmented variant with some melanocytes and melanin pigment in cells and macrophages.^{1084,1107} A racemiform and reticulated pattern of growth has been recorded.¹⁰⁸⁹

Duct-like structures are often present in the tumor. Some resemble eccrine or apocrine ducts, whereas others consist of several layers of concentric squamous cells with slit-like lumina. The stroma between the lobules varies from thin, delicate, vascularized cords of fibrous tissue to abundant focally hyalinized collagen. A myxoid or chondroid stroma is rarely present.

Immunohistochemistry demonstrates low-molecular-weight cytokeratin (CAM5.2) in most tumors. Some also express CEA and EMA.¹¹⁰⁸ There is some variability in the expression of the various keratin subtypes in different parts of the tumor.^{1109,1110} Smooth muscle actin and S100 protein were coexpressed in one case.¹¹¹¹

Figure 33.54 (A) Apocrine hidradenoma. (B) This lesion was previously classified as an eccrine hidradenoma. (C) Clear cells are prominent in this example. The nuclei tend to be smaller than those in eosinophilic cells. (H&E)

There has been a report of myoepithelioma arising in a hidradenoma of the scalp.¹¹¹² The myoepithelial component consisted of broad aggregates of spindled cells arranged in short fascicles, featuring eosinophilic cytoplasm and ovoid nuclei. Mitoses numbered 1 per 10 high-power fields, but there was no appreciable cytologic atypia.

These cells stained positively for S100, high- and low-molecular-weight cytokeratins, and smooth muscle myosin.¹¹¹² Myoepitheliomas are best known for occurring in association with mixed tumor of skin, and they can also be seen as an independent tumor, either monophasic or biphasic (adenomyoepithelioma). They are also seen in the setting of malignant mixed tumor or myoepithelial carcinoma (see later discussion).¹¹¹²

The malignant variant has an infiltrative growth pattern, frequent mitoses (although some overlap exists in the mitotic rate between benign and malignant variants),^{1101,1113} and sometimes angiolymphatic invasion.

On fine needle aspiration cytology, there are cells arranged in cohesive clusters, sometimes forming papillae. These cells are polygonal, with variable clear to eosinophilic or granular cytoplasm, oval nuclei with smooth contours, and distinct nucleoli.¹¹¹⁴

Electron microscopy¹¹¹⁵

The cells comprising the tumor are connected by desmosomes. The clear cells have abundant glycogen and few tonofilaments, whereas the other cell type has abundant tonofilaments and small amounts of glycogen.

Hidradenoma (poroid hidradenoma)

As noted previously, hidradenoma refers to a tumor that includes both an eccrine and an apocrine variant. The two are clinically indistinguishable. Both usually present as a solitary, solid or partially cystic nodule with a slight preponderance in females of middle age¹⁰⁸⁶ but with no site predilection. A case presenting on the vulva has been reported.¹¹¹⁶ Cases occurring in children are rare;^{1117,1118} a case has recently been reported in a 13-year-old boy.¹¹¹⁹ Hidradenoma averages 1–3 cm in diameter, but larger variants up to 6 cm or more in diameter have been recorded.^{977,1113,1120} The behavior of the eccrine variant is probably no different from that of the apocrine variant (see p. 943).

Histopathology

Despite their identical clinical appearances, the eccrine variant of hidradenoma differs histologically from the apocrine hidradenoma. Eccrine hidradenoma (poroid hidradenoma) is a circumscribed, non-encapsulated dermal tumor composed of poroid and cuticular cells.⁹⁷⁷ Ductal structures may form, particularly within the zones of cuticular cells. It has the architectural features of the apocrine hidradenoma but with the cytological characteristics of a poroma (Fig. 33.55).⁹⁷⁴ It lacks the polygonal, clear, and mucinous cells of the apocrine variant,⁷⁴⁶ although cases purported to be eccrine variants have contained clear cells.⁹⁷⁷ Sebaceous differentiation has been described,⁹⁸⁰ again calling into question the eccrine origin of such cases.

SYRINGOCYSTADENOMA PAPILLIFERUM

Syringocystadenoma papilliferum is an uncommon benign tumor of disputed histogenesis,¹¹²¹ with a predilection for the scalp and forehead.^{1122,1123} Less common sites of involvement are the chest,¹¹²⁴ upper arms,¹¹²⁵ male breast,¹¹²⁶ eyelids,¹¹²⁷ scrotum,¹¹²⁸ and thighs. There is an associated organoid nevus in approximately one-third of cases,¹¹²² and for this reason it is not always possible to be certain at what age the syringocystadenoma (syringoadenoma) papilliferum component developed.¹¹²⁹ Probably half are present at birth or develop in childhood.¹¹³⁰ A coexisting basal cell carcinoma is noted in 10% of cases,¹¹²² and there are two reports of an associated condyloma acuminatum^{1128,1131} and another of a verrucous carcinoma.¹¹³² A contiguous verrucous cyst and a tubulopapillary hidradenoma (apocrine adenoma) have also been present.^{1133,1134} Other congenital lesions have been associated with the

Figure 33.55 Poroid hidradenoma. This lesion has the cytological characteristics of a poroma, and it lacks polygonal, clear, or mucinous cells. Ductal structures can be identified within the tumor. (H&E)

presence of the tumor. Localization to a postoperative scar has been reported, but no histology was performed on the congenital lesion that was removed from this site 7 years earlier.¹¹³⁵

The tumor has a varied clinical appearance, most often presenting as a raised warty plaque or as an irregular, flat, gray or reddened area.¹¹³⁶ Linear papules and nodules are occasionally present.^{1125,1137,1138} The lesions measure 1–3 cm in diameter and are usually solitary. Alopecia accompanies those on the scalp.

There is increasing evidence for an apocrine histogenesis,^{1139,1140} but the possibility of an eccrine origin for a few cases seems likely. Another theory suggests the apoeccrine glands as the origin of this tumor.¹¹⁴¹ It may be derived from pluripotent cells.¹¹⁴² Allelic deletions have been reported at 9p21 (p16) and 9q22 (the patched gene).¹¹⁴³

Several examples of a malignant variant, **syringadenocarcinoma papilliferum**, have been reported.^{1144,1145} They have arisen on the scalp, back, chest, and in the perianal region.^{1146,1147} Some have been present for many years, suggesting the possibility of malignant transformation of a benign lesion.

Histopathology¹¹²²

The tumor is composed of duct-like structures that extend as invaginations from the surface epithelium into the underlying dermis (Fig. 33.56). These may be lined by squamous epithelium near the epidermal surface, with a transition to double-layered cuboidal and columnar epithelium below. Sometimes this latter epithelium partly replaces the overlying epidermis. At other times, the surface is composed of irregular papillary projections covered by stratified squamous epithelium. Rarely, there is no connection with the epidermis. Such cases are thought to be connected to the follicular infundibulum.¹¹⁴⁸ An unusual keratotic lesion, thought to be derived from the apocrine acrosyringium, has been reported in association with syringocystadenoma papilliferum.¹¹⁴⁹ It showed hyperkeratotic columns surrounded by acanthotic epidermis with features of trichilemmal keratinization. The term ‘**apocrine acrosyringial keratosis**’ was used for this associated proliferation.¹¹⁴⁹

The dilated and contorted ducts may lead into cystic spaces, into which villous projections of diverse size and shape protrude. The ducts and papillary projections are usually covered by an inner layer of columnar epithelium and an outer layer of cuboidal or flattened cells. Goblet cells may be present.¹¹⁵⁰

Figure 33.56 (A) Syringocystadenoma papilliferum. Irregular papillary projections protrude into the invaginations of the surface epithelium. The stroma contains numerous plasma cells. (B) This malignant variant has similarity to its benign counterpart. (H&E)

The stroma of the papillary processes contains connective tissue, dilated vessels, and, characteristically, numerous plasma cells admixed with a few lymphocytes (Fig. 33.57). The underlying dermis also contains a few inflammatory cells.

There may be underlying dilated sweat glands and, occasionally, dilated apocrine glands. In cases associated with an organoid nevus, apocrine glands are said to be always present.¹¹⁵¹ This apocrine component may resemble a tubular apocrine adenoma. Sebaceous differentiation has been reported in an apocrine adenoma associated with syringocystadenoma papilliferum.¹¹⁵²

Carcinoembryonic antigen is usually present in the epithelial cells.^{750,751} GCDFP-15 is variably positive in the tumor cells.⁷⁵² The luminal columnar cells express CK7, and more than 70% are positive for CK19. The basal cuboidal cells usually express CK7 also, but the expression of CK19 by these cells is variable.¹¹⁴² IgA and secretory component have also been demonstrated in these cells, and it has been suggested that the cells attract plasma cells by a similar mechanism to that utilized by glands of the secretory immune system.¹¹⁴⁰ Further evidence for the existence of an eccrine variant comes from a study of the eccrine-specific marker IKH-4, which has labeled one case.⁷⁴⁹

Figure 33.57 Syringocystadenoma papilliferum. Papillary structures have fibrin cores that contain numerous plasma cells. (H&E)

Although Hashimoto found evidence ultrastructurally for an eccrine origin,¹¹⁵³ Niizuma suggested that the tumor differentiates toward the intrafollicular and intradermal duct of the embryonic apocrine gland.¹¹³⁹ Apocrine differentiation was also found in another ultrastructural study.¹¹⁴²

Syringadenocarcinoma papilliferum lacks precise morphological definition, but some have a close but cytologically malignant similarity to their benign counterpart (see **Fig. 33.56b**). Solid areas of tumor may be present, in addition to the cystic and papillary areas.^{1144,1145} In one instance, a ductal sweat gland carcinoma was reported arising in syringocystadenoma papilliferum;¹¹⁵⁴ another case has subsequently been challenged.^{1155,1156} They express CEA and BRST-1.¹¹⁴⁷ GCDFP-15 may also be positive.

This group is expanding as tumors previously regarded as being of eccrine origin are reclassified as apocrine tumors. The following tumors are considered here:

- Tubular adenoma (apocrine adenoma)
- Hidradenoma papilliferum
- Apocrine mixed tumor (apocrine chondroid syringoma)
- Myoepithelioma (often apocrine associated).

Their association with follicular tumors and the occasional presence of sebocytes and other structures indicate that the cylindroma and its frequent associate, the spiradenoma, are also of apocrine origin, as stated by Ackerman and colleagues. There is less convincing evidence that syringomas are of apocrine origin. At this stage, syringomas are considered with the eccrine tumors.

TUBULAR APOCRINE ADENOMA

Tubular adenoma is a very rare tumor that may be found in the axilla,¹¹⁵⁷ cheek,¹¹⁵⁸ and breast¹¹⁵⁹ or in association with an organoid nevus.^{1160,1161} Lesions of the vulval and perianal area reported as apocrine adenoma¹¹⁶² and apocrine fibroadenoma probably represent variants of what are now called '**adenomas of anogenital mammary-like glands**' (see p. 951).

The *tubular apocrine adenoma*, first described by Landry and Winkelmann in 1972, is part of this spectrum. It has a predilection for the scalp. Furthermore, tumors reported by Rulon and Helwig as papillary eccrine adenomas have been regarded by some authors as examples of

Figure 33.58 Tubular apocrine adenoma. (A) There are multiple tubular structures lined by apocrine-type epithelium. (B) Papillary projections project into the lumina of some tubules. (H&E)

apocrine adenomas, whereas others have regarded them as separate entities on the basis of different sites of origin and their microscopic and immunohistochemical characteristics.^{1163,1164} They are considered separately here. An origin from apoecrine glands has also been suggested to explain their dual differentiation.¹¹⁶⁵

Requena, Kiryu, and Ackerman use the term '*tubular adenoma*' for this spectrum of cases and include tumors known as papillary eccrine adenoma.⁷⁴⁶ The term '*tubulopapillary hidradenoma*' has also been used for this spectrum.¹¹³⁴

Apocrine cystadenoma, which differs from apocrine hidrocystoma by having true papillae with a fibrous core, is now included as part of this spectrum.⁸⁴⁶

Tubular adenomas are slowly growing, circumscribed nodules situated in the dermis or subcutaneous tissue. They are treated by surgical excision; Mohs micrographic surgery has been used for their removal.¹¹⁶⁶

Histopathology^{1167–1169}

The tumor is composed of circumscribed lobules of well-differentiated tubular structures situated in the dermis but sometimes extending into the subcutis (**Fig. 33.58**). A transition to normal apocrine glands may be

present. The tubules have apocrine features with an inner layer of cylindrical cells, often showing ‘decapitation’ secretion. Papillae devoid of stroma project into the lumina of some tubules. There is often an outer layer of flattened cuboidal cells. Follicular and sebaceous differentiation are rare, but their presence adds support to the view that this tumor is derived from the folliculosebaceous–apocrine germ.¹¹⁷⁰ Occasional comedo-like conduits extend into the epidermis and form a communication with some of the tubules of the tumor.¹¹⁷¹ The epidermis may be hyperplastic. The stroma consists of fibrous tissue with only a paucity of inflammatory cells.

Immunoperoxidase studies have shown that the tumor cells contain cytokeratin; human milk protein and CEA are localized to the apical region of the cells.¹¹⁷²

Electron microscopy

Ultrastructural features confirm the apocrine nature of apocrine adenoma; luminal cells show vacuolar change, lipid granules, and multiple microvilli projecting into the lumen.¹¹⁶⁸ Most of the cells are rich in organelles such as mitochondria and endoplasmic reticulum, and they have a prominent Golgi apparatus. Cases with some eccrine features have been reported.¹¹⁶⁵

Differential diagnosis

The stroma of tubular apocrine adenoma stands in contrast to syringocystadenoma papilliferum, in which inflammatory cells, particularly plasma cells, are prominent. However, cases of tubular adenoma have been reported with features of syringocystadenoma papilliferum in the upper part of the lesion.^{1163,1172–1175} Apocrine cystadenomas are considered part of this spectrum of ‘tubular adenomas’. They are simpler lesions, always cystic, with one or several cystic apocrine structures with true papillae (papillae with a fibrous core) protruding into the lumen. They are more cystic and less complex than cases of tubular apocrine adenoma.⁸⁴⁶

These tumors differ from apocrine adenocarcinomas by lack of infiltration of surrounding tissues and by less marked cytological atypia. Myoepithelial cells are usually present in adenomas, whereas they are absent in adenocarcinomas.¹¹⁵⁸

HIDRADENOMA PAPILLIFERUM

Hidradenoma papilliferum is a variant of apocrine adenoma with specific morphology. It is almost always found in the vulval and perianal regions.^{1176,1177} There are reports of ectopic lesions developing on the face, scalp, orbit,¹¹⁷⁸ nose,^{1179,1180} breast,^{1181,1182} chest,¹¹⁸³ back,¹¹⁸⁴ abdomen,¹¹⁸⁵ eyelid,¹¹⁸⁶ auditory canal,¹¹⁸⁷ and arm. Approximately 30 ectopic cases have now been reported. It presents usually as a solitary nodule, usually less than 1 cm in diameter and usually in middle-aged women. Cases in males have been recorded.¹¹⁸³

Histopathology¹¹⁸⁸

The tumor is usually partly cystic and has both papillary and glandular areas (Fig. 33.59). The papillae often have an arborizing trabecular pattern; the glandular structures vary in size. Two types of epithelium are noted in both papillary and glandular areas. Usually, the cells are tall and columnar with pale eosinophilic cytoplasm and nipple-like cytoplasmic projections on the surface. An underlying thin myoepithelial layer is often present. In approximately one-third of lesions, cuboidal cells with eosinophilic cytoplasm and small round nuclei, resembling apocrine metaplasia as seen in the breast, are present in some areas of the tumor. Oxyphilic metaplasia is uncommon; it may lead to a misdiagnosis of malignancy.¹¹⁸⁹ The mitotic index is variable, but it can be high. However, it does not predict a more aggressive outcome.¹¹⁹⁰

A case of hidradenoma papilliferum with mixed histological features of syringocystadenoma papilliferum and anogenital mammary-like

Figure 33.59 Hidradenoma papilliferum with papillary and glandular areas. (H&E)

glands has been reported.¹¹⁹¹ It was postulated that the tumor might have developed from these mammary-like glands. Other complex, or composite, tumors have had features of hidradenoma papilliferum, syringocystadenoma papilliferum, and anogenital mammary-like glands¹¹⁹² or hidradenoma papilliferum and fibroadenoma, with pseudoangiomatic stromal hyperplasia and multinucleated giant cells.¹¹⁹³

PAS-positive diastase-resistant granules are present in the apices of the large cells, and material in the glandular spaces stains with the colloidal iron method for acid mucopolysaccharides. GCDPF-15, a sensitive marker for apocrine differentiation, is usually positive.¹¹⁹¹

Dermoscopy of one lesion on the scalp showed a blue, homogeneous pattern, resembling that of blue nevus or metastatic melanoma.¹¹⁹⁴

Electron microscopy

Electron microscopy has shown characteristic secretory granules and ‘decapitation’ secretion.¹¹⁹⁵

Differential diagnosis

The exuberant proliferation of tubules can raise concerns about malignancy, particularly if the lesion has been traumatized. However, the characteristic sharply circumscribed profile of these lesions is a reliable clue to the diagnosis of hidradenoma papilliferum. Hidradenoma papilliferum has been reported with a ductal carcinoma *in situ* component.¹¹⁹⁶ This differs from hidradenocarcinoma papilliferum, the malignant equivalent of hidradenoma papilliferum, in which invasive carcinoma is present.¹¹⁹⁶ Reports of such cases remain elusive. Despite similarities in the name, hidradenoma papilliferum does not closely resemble the other lesions referred to as hidradenoma – so-called nodular hidradenoma or solid-cystic hidradenoma (discussed previously). The latter lack the overall sharp circumscription of hidradenoma papilliferum, may show epidermal connections, lack complex interconnecting papillae, and often have solid areas composed of monotonous (and sometimes clear) cuboidal cells.

APOCRINE MIXED TUMOR (APOCRINE CHONDROID SYRINGOMA)

More than 30 years ago, it was suggested that chondroid syringomas (cutaneous mixed tumors), as they were called, had eccrine and apocrine variants.¹¹⁹⁷ In 1989, Ackerman’s group supported this contention.¹¹⁹⁸ This view is now universally accepted.

Apocrine mixed tumor (chondroid syringoma, apocrine type) is an uncommon tumor, usually occurring as a solitary, slowly growing nodule on the head or neck of the middle-aged and elderly.¹¹⁹⁹ It has also been reported in a child.¹²⁰⁰ Uncommon sites include the vulva,¹²⁰¹ shoulder,¹¹⁰⁰ ear,¹²⁰² and extremities.¹⁰⁹⁴ There is a male predilection. Most tumors are well circumscribed and measure 0.5–3 cm in diameter.

A series of 18 cases of apocrine mixed tumors of the skin with architectural and/or cytological atypia has been described (see later).¹²⁰³ They presented as solitary nodules, usually 0.4–2 cm in diameter (although one was 12 cm in diameter), on the face and, less commonly, the lower extremities and inguinal region. No recurrences or metastases were documented on clinical follow-up.¹²⁰³ True malignant variants of apocrine mixed tumor are extremely rare.

Histopathology

Apocrine mixed tumors are circumscribed dermal tumors with an epithelial component distributed through a myxoid, chondroid, and fibrous stroma (Fig. 33.60). The epithelial component includes clusters and solid cords of cells as well as ductal structures, sometimes branching, lined by two layers of cuboidal cells.¹²⁰⁴ Some of the ducts are variably dilated, and keratinous cysts may form.¹²⁰⁵ The finding of an apocrine duct in continuity with this tumor is further support for an apocrine origin.¹²⁰⁶ Eosinophilic globules composed of collagen (collagenous spherulosis) may be found in the lumina of the glandular elements. This change was present in the stroma in one case.¹²⁰⁷ Solid islands of squamous epithelium may be present. Focal calcification, ossification,¹²⁰⁸ adipose metaplasia, and sebaceous and matrical differentiation are sometimes present.^{1209–1213} When adipose tissue is a conspicuous component, the term **lipomatous (apocrine) mixed tumor** is used.^{1214–1218} Hyaline epithelial cells are uncommon.^{1219,1220} Rare cases are composed almost exclusively of these hyaline cells, which have a ‘plasmacytoid’ appearance because of the peripheral displacement of the nucleus.^{1221,1222} Such cases have been called hyaline cell-rich chondroid syringomas, but hyaline cell-rich apocrine mixed tumor would now be more appropriate (Fig. 33.61). Several examples of apocrine mixed tumor have shown intravascular or intralymphatic tumor deposits; these consisted of collections of hyaline cells and were immunoreactive for cytokeratins and (partly) S100 protein and calponin, therefore having the phenotype of myoepithelial cells.¹²²³ No recurrence or metastasis was observed during the follow-up period that ranged from 2 to 21 years.¹²²³

In a large series of 244 cases of apocrine mixed tumor of the skin (mixed tumor of the folliculosebaceous–apocrine complex), all types of differentiation along the lines of the folliculosebaceous–apocrine unit were found.¹²¹² The spectrum of metaplastic changes in the epithelial component included squamous, mucinous, oxyphilic, columnar, and hobnail metaplasia, as well as clear cell change and cytoplasmic vacuolization.¹²¹² Myoepithelial variability was also demonstrated. These changes have already been discussed.¹²²⁴

The term **‘atypical mixed tumor’** has been suggested for tumors with borderline features of malignancy, such as an infiltrative edge, but that do not develop metastasis after follow-up.¹²²⁵ The series of 18 cases with architectural and/or cytological atypia, referred to previously, was characterized by good circumscription and lack of capsular breach or hypercellularity.¹²⁰³ Pushing borders were sometimes seen. All but 1 case were of the hyaline-cell rich type.¹²⁰³ There were multinucleated, bizarre, hyperchromatic cells in hyaline cell areas. Cells were negative for p53. Ultrastructurally, hyaline cells exhibited features consistent with myoepithelial differentiation.¹²⁰³

The cells express CEA and cytokeratin, whereas cells in the outer layer of the tubular structures contain vimentin and S100 protein.^{1198,1226–1228} This coexpression of CEA and cytokeratins suggests that the keratin cysts may contain cells differentiating toward the intrafollicular portion of the apocrine duct.¹²²⁹ Extracellular matrix

Figure 33.60 (A) Apocrine mixed tumor. (B) It is composed of ductal structures set in a myxoid and chondroid matrix. (H&E)

Figure 33.61 (A) Hyaline cell-rich apocrine mixed tumor (chondroid syringoma). (B) The hyaline cells have a plasmacytoid appearance. (H&E)

components, such as type IV collagen, laminin, fibronectin, and tenascin, are prominently expressed in the chondromyxoid matrix.¹²³⁰ Type II collagen, which is expressed almost exclusively in cartilage, has been found not only in the stroma but also in epithelial portions of the tumor.¹²³¹ The chondroid matrix expresses BM-1.¹²³² Scattered Merkel cells are uncommon, as demonstrated by CK20 staining.¹²³³ The monoclonal antibody G-81, which recognizes a component of dermcidin, a constituent of eccrine sweat glands, has stained some cases of apocrine mixed tumor. This suggests either dual eccrine/apocrine differentiation in some of these tumors or lack of specificity of the antibody.¹²³⁴

Electron microscopy

Ultrastructural studies have shown tubuloalveolar spaces lined by ductal epithelium.^{1205,1235} There are myoepithelial cells, which appear to be responsible for producing the chondroid material.¹²³⁶ The epithelial cells in the solid nests of cells show intracytoplasmic luminal formation.¹²³⁶

ECCRINE MIXED TUMOR (ECCRINE CHONDROID SYRINGOMA)

Eccrine mixed tumor (chondroid syringoma, eccrine type) is a rare tumor that was formerly included with the apocrine variant of mixed

tumor as a chondroid syringoma. It is found as a solitary, slowly growing nodule on the head or extremities of the middle-aged and elderly. Local recurrence occurs only if the tumor is incompletely excised. A recent large study of 50 cases of eccrine mixed tumor was reported by Kazakov *et al.*¹²³⁷ More than half of the cases arose in the head and neck region, with a female:male ratio of 1.5:1. The mean age was 61 years; all tumors were surgically excised.

Histopathology

The eccrine mixed tumor has small, nonbranching tubules composed of a single layer of round, ovoid, or cuboidal cells with eosinophilic cytoplasm, some with a plasmacytoid appearance.¹²³⁷ Some tadpole-like structures resembling syringoma are also seen. Confluence of tubules forms small cribriform structures. Unusual features include clear cell changes, pseudorosettes, and physaliphorous-like cells. Stromal features include myxoid or chondroid areas, fibrosis, lipomatous metaplasia, calcification, and bone formation arising through enchondral ossification.¹²³⁷ (Fig. 33.62). The tumor is well circumscribed and may extend into the subcutis. Immunohistochemistry shows diffuse CK7 and S100 positivity, glial fibrillary acidic protein in some cases, EMA staining confined to luminal surfaces of tubules and secretory material, and BRST2 staining of secretory material and some tubules. The authors of this study readily acknowledge the difficulty of proving the eccrine nature of these lesions, although none of their cases exhibited evidence for primary epithelial germ differentiation.¹²³⁷

Differential diagnosis

The combination of epithelial and mesenchymal elements is unique among cutaneous tumors. However, mixed tumors of salivary gland can have a close microscopic resemblance, and some deeply located mixed tumors obtained from the facial region may in fact represent salivary mixed tumors.¹²³⁸ Chondroma, osteoma, or mesenchymal hamartomas of skin might also be considered, especially in cases in which the stromal changes predominate,¹²³⁹ but these lack the epithelial components of mixed tumor.

MYOEPITHELIOMA

Myoepitheliomas are exceedingly rare cutaneous tumors that present as dome-shaped, exophytic nodules on the face, neck, extremities, or trunk.^{1240–1243} They may occur at any age, but in the study of 14 cutaneous cases by Hornick and Fletcher, the median age was 22.5 years (range, 10–63 years).¹²⁴⁴ Myoepitheliomas also occur in salivary glands,¹²⁴⁵ deep soft tissues,¹²⁴⁶ and other organs. Parotid gland myoepitheliomas may present as a subcutaneous mass.¹²⁴⁵ They are derived from myoepithelial cells that are found in the skin as a discontinuous peripheral layer around eccrine and apocrine glands.¹²⁴¹ Their contraction aids in the delivery of their secretory products. Focal myoepithelial proliferation is not uncommon in apocrine and eccrine mixed tumors. Sometimes the myoepithelial proliferation constitutes a significant component of the mixed tumor, justifying a designation of myoepithelioma.¹²⁴³ Some of the mixed tumors and myoepitheliomas of soft tissue reported by Fletcher and colleagues were probably apocrine mixed tumors with areas of myoepitheliomatous change.¹²⁴⁶ Myoepithelial tumors of soft tissue are not considered further; Hornick and Fletcher have published 101 cases.¹²⁴⁷

Cutaneous myoepitheliomas range in size from 0.5 to 2.5 cm in diameter.¹²⁴⁴

The lesions are almost invariably benign; local recurrences have been recorded.¹²⁴⁴ Malignant cases have been designated **myoepithelial carcinomas**.¹²⁴³ They have a very low metastatic potential.^{1243,1244,1248} Approximately five cases have been reported.¹²⁴⁹

Figure 33.62 (A) Eccrine mixed tumor (chondroid syringoma of eccrine type). (B) This variant is composed of small, nonbranching ducts set in a myxoid and chondroid stroma. (H&E)

A subset of cutaneous and soft tissue myoepitheliomas with tubuloductal differentiation show *PLAG1* gene rearrangements and sometimes *LIFR-PLAG1* fusion – features held in common with pleomorphic adenomas of salivary gland.¹²⁵⁰

Histopathology

Myoepitheliomas are circumscribed, non-encapsulated tumors situated in the dermis or subcutis. Dermal tumors may extend into the subcutis. They are composed of spindle-shaped, epithelioid, histiocytoid, and plasmacytoid (hyaline) cells.¹²⁵¹ The cells usually have pale eosinophilic cytoplasm and relatively monomorphous ovoid nuclei. Mitoses are usually uncommon or absent. The mitotic rate is relatively high in cases that recur or are frankly malignant.¹²⁴⁴ Some tumors have very little stroma, whereas others have a myxoid or collagenous hyalinized stroma.

Immunohistochemistry shows that the cells express vimentin, S100 protein, EMA, and, often, smooth muscle actin, muscle-specific actin (HHF35), glial fibrillary acid protein (GFAP), and calponin.^{1241,1243,1244} Keratin staining is quite variable.¹²⁵² In a recent case of cutaneous myoepithelioma, there was dot-like paranuclear staining for cytokeratin MNF116.¹²⁵³ In the cutaneous cases reported by Hornick and Fletcher, all five cases without keratin staining were diffusely positive for EMA.¹²⁴⁴

The rare **adenomyoepithelioma** combines glandular sweat gland elements with myoepithelial cells.^{1254,1255} Adipose tissue is rarely a predominant element in another variant.¹²⁴⁴

The exceedingly rare **myoepithelial carcinoma** is usually a larger tumor with cellular atypia and a high mitotic rate. Central necrosis is often present.¹²⁴⁹

TUMORS OF MODIFIED APOCRINE GLANDS

The glands of Moll on the eyelid and the ceruminous glands of the external ear are examples of modified apocrine glands. The breast can also be regarded as a modified apocrine gland. Ectopic mammary glands do occur (see later).

EROSIVE ADENOMATOSIS OF THE NIPPLE

Erosive adenomatosis (florid papillomatosis, papillary adenoma) is a rare benign tumor involving the nipple that may clinically mimic Paget's disease.^{1256,1257} It is thought to arise from the ducts of the nipple. It may rarely occur in males and in children.^{1258,1259}

Total excision of the tumor, including the nipple, has been the usual treatment modality because of the high incidence of recurrence when removal is incomplete. Mohs micrographic surgery can be used, with preservation of the nipple, in cases that are not advanced.¹²⁶⁰

Histopathology¹²⁶¹

This dermal tumor is a well-circumscribed non-encapsulated lesion with an adenomatous configuration (Fig. 33.63). Some of the ducts have papillary projections into the lumen, and a few show cystic dilatation. The lining epithelium is of apocrine secretory type, and there is usually a backing of myoepithelial cells. Some ducts connect with the surface epithelium; squamous epithelium may extend into them.

The fibrous stroma sometimes contains a mild inflammatory infiltrate, which may be rich in plasma cells.

CERUMINOUS ADENOMA AND ADENOCARCINOMA

The ceruminous glands are modified apocrine glands in the external auditory canal. They give rise to rare tumors in which the distinction

Figure 33.63 Erosive adenomatosis of the nipple composed of duct-like structures of varying size. (H&E)

between adenoma and adenocarcinoma may be difficult on histological grounds.^{1262–1264} For this reason, the term ceruminous gland tumor has been suggested.¹²⁶⁵ The term ‘ceruminoma’ has been used in the past not only for the ceruminous adenoma and adenocarcinoma but also for adenoid cystic carcinomas and mixed tumors of the auditory canal. The term is best abandoned.

A series of 41 cases of ceruminous adenoma was reported from the Armed Forces Institute of Pathology (AFIP) in 2004.¹²⁶⁶ There was a slight male predominance; the mean age was 54.2 years (range, 24–85 years).¹²⁶⁶ Patients usually presented clinically with a painless mass of the outer half of the external auditory canal. Hearing loss was present in approximately 25% of cases. Surgical excision was used for all lesions; recurrence occurred in four patients due to incomplete excision. No malignant cases were reported.

Histopathology

In the AFIP series, 36 cases were classified as ceruminous adenomas, 4 as ceruminous pleomorphic adenomas, and 1 as syringocystadenoma papilliferum.¹²⁶⁶ The tumors were composed of a tubuloglandular proliferation of inner ceruminous cells subtended by a spindled to cuboidal myoepithelial layer. The luminal cells expressed CK7 and CD117, whereas the basal cells were highlighted with CK5/6, S100 protein, and p63.¹²⁶⁶ In a recent case, tumor cells of ceruminous adenoma were positive for Glut-1, HIF-1- α , PI3K, and p-Akt, indicating a role for the PI3K/Akt pathway in these tumors.¹²⁶⁷

Fine needle aspiration cytology of ceruminous adenoma shows myoepithelial cells and clusters of polygonal cells with granular cyanophilic cytoplasm and containing yellow-green ceroid granules, confirming the ceruminous character of the tumor.¹²⁶⁸

Differential diagnosis

The lack of necrosis, cytologic atypia, and mitotic activity distinguishes ceruminous adenoma from ceruminous adenocarcinoma or adenoid cystic carcinoma.¹²⁶⁷

TUMORS OF ANOGENITAL MAMMARY-LIKE GLANDS

Mammary-like glands are a newly recognized variant of cutaneous adnexal gland found in the anogenital region.¹²⁶⁹ They resemble mammary glands, although they have variously been regarded in the

past as modified eccrine or apocrine glands. Adenosis,¹²⁷⁰ hyperplasia,¹²⁷¹ adenomas^{1269,1272} (including fibroadenomas),^{1273–1278} and adenocarcinomas¹²⁷⁹ may arise in these glands. More than 20 cases of adenocarcinoma of mammary-like glands of the vulva have now been recorded.^{1280,1281} An adenocarcinoma of tubulolobular type is a rare variant.¹²⁸² Decapitation secretion is sometimes present in tumors of this region.¹²⁸³ These glands possess receptors for estrogen and progesterone proteins that help to distinguish them from classic eccrine and apocrine glands. Mammary-like sweat glands can occur in other parts of the body, outside the milk line. Cases of breast-like lesions arising in the skin of the thigh, scalp, eyelid, and umbilicus have been reported.^{1284,1285} They presumably arose in ectopic mammary-like sweat glands. The origin of the facial apocrine fibroadenoma reported in a male is speculative.¹²⁸⁶ It did not express estrogen or progesterone receptors and may represent a second type of apocrine fibroadenoma.¹²⁸⁶

Tumors of the anogenital mammary-like glands are comparatively common compared to lesions of Bartholin’s gland and minor vestibular glands.^{1287,1288} Nodular hyperplasia and adenomas of Bartholin’s gland have been reported, although the distinction between the two is not always clear-cut.^{1287,1289}

COMPLEX ADNEXAL TUMORS

The term ‘complex adnexal tumors’ is proposed for those tumors, including hamartomas, in which differentiation toward more than one adnexal structure is present. The most important lesion in this group is the organoid nevus (nevus sebaceus of Jadassohn), in which abnormalities of all adnexal structures as well as of the epidermis may be present. Other tumors in this group include the adnexal polyp of neonatal skin,¹²⁹⁰ combined adnexal tumor,¹²⁹¹ poroma-like adnexal adenoma,^{698,700} sebaceous epithelioma with sweat gland differentiation,⁶³⁴ and hemifacial mixed appendage tumor.¹²⁹² The linear eccrine nevus with comedones (see the discussion of eccrine hamartomas, p. 933) could also have been included. The hamartoma of the folliculosebaceous-apocrine unit was composed of a mesenchymal component of smooth muscle and myofibroblastic cells, encased within which were large infundibular structures, and grouped and scattered duct-like, glandular and tubular elements resembling syringoma and tubular apocrine adenoma.¹²⁹³

ORGANOID NEVUS (NEVUS SEBACEUS)

Organoid nevus (nevus sebaceus of Jadassohn) is a complex hamartoma involving not only the pilosebaceous follicle but also the epidermis and often other adnexal structures.^{1294,1295} Some authors regard the organoid nevus as a group generic term that includes not only the organoid nevus (nevus sebaceus) but also nevus comedonicus, porokeratotic eccrine nevus, Becker’s nevus, trichilemmal cyst nevus,¹²⁹⁶ and phacomatosis pigmentokeratotic.^{1297,1298} Organoid nevus evolves through different stages. Nearly all lesions are on the scalp, forehead, or face. The labia minora is an exceedingly rare site.¹²⁹⁹ It is present at birth or develops in early childhood. Familial cases have been recorded.^{1300–1302} Most lesions are plaques 1–6 cm in diameter. A lesion 9.5 cm in diameter, with a cerebriform surface, has been reported on the scalp.¹³⁰³ Linear or zosteriform patterns are uncommon.

The linear sebaceous nevus syndrome (organoid nevus phacomatosis, Schimmelpenning–Feuerstein–Mims syndrome; OMIM 163200) is characterized by organoid nevi, often on the face,¹³⁰⁴ abnormalities of the central nervous system and eyes, oral lesions,^{1305,1306} and skeletal defects.^{1307–1309} The organoid nevi are sometimes arranged along the lines of Blaschko. All cases have been sporadic. It is thought to be caused by an autosomal dominant lethal mutation that survives by somatic mosaicism.¹³⁰⁵ This entity has been associated with stroke syndrome.¹³¹⁰

Using whole exome and targeted sequencing, it has been found that *HRAS* mutations predominate in nevus sebaceus and that *HRAS* and *KRAS* mutations may be sufficient to cause nevus sebaceus without genome instability, loss of heterozygosity, or secondary mutation.^{1311,1312} The data from these and other studies¹³¹³ indicate that both epidermal and sebaceous nevi are associated with activating *HRAS* p.Gly13Arg and *KRAS* p.Gly12Asp mutations. Furthermore, the evidence seems to support the current view that basaloid tumors arising from nevus sebaceus are trichoblastomas rather than basal cell carcinomas because the latter arise from Hedgehog pathway dysregulation and not *RAS* mutations.¹³¹²

Organoid nevi are usually hairless, yellow or waxy in color, with a smooth, warty, or mamillated surface. Eczematous changes, sometimes obscuring the lesion, have been reported in a few cases – an example of Meyerson's phenomenon.¹³¹⁴ There are some reports of patients with large organoid nevi of the scalp with associated neuroectodermal and other defects,^{1315–1317} but these associations were not present in the large series of Mehregan and Pinkus,¹²⁹⁵ and of Wilson Jones and Heyl.¹³¹⁸ Only a low incidence of neurological manifestations was found in the 196 cases of organoid nevi reported by Davies and Rogers.¹³¹⁹ The term SCALP syndrome (sebaceous nevus syndrome, CNS symptoms, aplasia cutis, limbal dermoid, and pigmented nevus with neurocutaneous melanosis) has been used for several patients who presented with these neurocutaneous features.¹³²⁰ **Phacomatosis pigmentokeratotica** is characterized by the coexistence of an organoid nevus with sebaceous differentiation arranged along Blaschko's lines and a speckled lentiginous nevus showing a checkerboard pattern, in association with skeletal and neurological abnormalities.^{1297,1298} One case has been reported in association with hypophosphatemic rickets, pheochromocytoma, and multiple basal cell carcinomas.¹²⁹⁷ Other associated abnormalities have included segmental neurofibromatosis,¹³²¹ retinoblastoma with associated lipomas and a meningioma,¹³²² and tuberous sclerosis.¹³²³ Tumors such as basal cell carcinoma, trichoblastomas, syringocystadenoma papilliferum, and hidradenomas may develop in organoid nevi in adults.¹³²⁴ Syringocystadenoma papilliferum is the most frequent tumor to develop in organoid nevi.¹³⁰⁸ Up to four different tumors may be present.¹³²⁵ Recent studies have confirmed that the vast majority of basaloid neoplasms arising in organoid nevi are trichoblastomas and not basal cell carcinomas as once thought.^{1308,1326–1328} The occurrence of pigmented trichoblastomas in one case mimicked a malignant melanoma clinically.¹³²⁹ Other rare associations include leiomyoma,¹³³⁰ syringoma, spiradenoma,¹³³¹ squamous cell carcinoma, nevoid growths of melanocytes,¹³³² keratoacanthoma, porocarcinoma,¹³³³ and various sebaceous and apocrine tumors,^{1318,1334–1336} including an apocrine adenocarcinoma that metastasized.¹³³⁷ Many of the associated tumors do not correspond precisely with described entities.¹²⁹⁴

Epidermodysplasia verruciformis-associated and genital-mucosal HPV DNA have been found in a significant number of cases of organoid nevi (nevus sebaceus of Jadassohn).¹³³⁸ However, in another group of 16 cases, analysis of nevus sebaceus tissue samples using type-specific, real-time polymerase chain reaction (PCR) for HPV-6, -11, -16 and -18 and using conventional PCR with modified general primers for broad-range HPV detection failed to detect HPV DNA in any of the samples.¹³³⁹

Although organoid nevi are often removed for cosmetic purposes, it has been stated that the low incidence of supervening malignancy does not justify the systematic removal of organoid nevi.¹³⁰⁸ Another article has recommended removal with a clearance of 2 or 3 mm 'because of the development of various carcinomas'.¹³⁴⁰

Histopathology^{1295,1318,1341}

In infants and young children, the dominant feature is the presence of immature and abnormally formed pilosebaceous units, which may also

Figure 33.64 Organoid nevus. The pilosebaceous follicles are small and abnormally formed. A few apocrine glands are present in the lower dermis. (H&E)

Figure 33.65 Organoid nevus. The epidermis shows features of an epidermal nevus, whereas the dermal changes are not striking in this area. (H&E)

be reduced in number (**Fig. 33.64**). The epidermal changes are usually mild, with some acanthosis and mild papillomatosis. Around puberty, there is enlargement of the sebaceous glands, which are often located abnormally high in the dermis, with an increased number of closely set lobules and malformed ducts. Some lobules may be incompletely lipidized. Sebaceous glands are sometimes reduced or even absent at this age. Hair follicles are usually vellus rather than terminal, and they are often reduced in number. The follicular dysgenesis and hair follicle numbers are easier to assess in lesions from the scalp than from other sites. The epidermis is now more papillomatous and acanthotic. At other times, the epidermal pattern may resemble a seborrheic keratosis, an epidermal nevus, or acanthosis nigricans (**Fig. 33.65**); rarely, there is pseudoepitheliomatous hyperplasia, a keratoacanthoma-like proliferation,¹³⁴² or epidermal downgrowths showing both apocrine and sebaceous differentiation.¹³⁴³ In the cases with eczematous change, eosinophilic spongiosis was observed.¹³¹¹ Apocrine glands are present in up to half of the cases, and sometimes the duct or secretory unit is dilated. Calcification within the apocrine glands has been reported.^{1344,1345} Eccrine glands may be reduced in number or show focal dilatation of the duct or secretory gland. In approximately 20% of cases, 'apocrine' glands are present, but they have been said to represent eccrine glands with variable apocrine metaplasia rather than the separate category of sweat glands usually included under this designation.¹³⁴⁶ This explanation does not fit well with the embryological derivatives of the primary epithelial germ – follicular, sebaceous, and apocrine.

The dermis is often thickened, particularly the adventitial dermis. There may be a slight increase in vascularity and a reduction in elastic fibers. Immature adipose tissue and extramedullary hematopoiesis

have been reported.¹³⁴⁷ Lesions with meningotheelial and muscular components are usually classified as rudimentary meningoceles or meningotheelial hamartomas (see p. 1059).¹³⁴⁸ A mild chronic inflammatory cell infiltrate of lymphocytes and plasma cells is often present. Merkel cells are increased in cases with follicular germ structures or with a superimposed trichoblastoma.¹³⁴⁹

In older patients, other tumors may develop, as mentioned previously. These may include syringocystadenoma papilliferum, which sometimes occupies only a small area of the entire nevus.

ADNEXAL POLYP OF NEONATAL SKIN

The adnexal polyp of neonatal skin is a small, usually solitary lesion occurring mostly on the areola of the nipple of the neonate.^{545,1290} It was present in 4% of 3257 newborn infants in the one Japanese study of this entity, but it has received little attention in the literature. It drops off in the first week of life. Histologically, it contains hair follicles, eccrine glands, and vestigial sebaceous glands.

COMBINED ADNEXAL TUMOR

The term ‘combined adnexal tumor’ has been used for a tumor with differentiation toward the formation of sebaceous glands and pilar and sweat duct structures.¹²⁹¹ It has also been applied to a tumor showing only pilar and sweat duct structures, but the case was probably a microcystic adnexal carcinoma.¹³⁵⁰ Apocrine, sebaceous, and pilar (follicular) differentiation has been reported in apocrine mixed tumors of the skin. This combination of structures has also been reported in a pigmented hamartoma of the eyelid.¹³⁵¹ Embryologically, this combination of structures is explicable because all three are derivatives of the primary epithelial germ.¹³⁵² Notwithstanding this explanation, tumors with all four patterns of differentiation (pilar, sebaceous, apocrine, and eccrine) have been described.¹³⁵³ A composite adnexal tumor of the penis showed a combination of syringocystadenoma papilliferum, trichilemmoma, and eccrine ductal proliferation.¹³⁵⁴ Note that divergent differentiation is sometimes seen in various eccrine carcinomas. The term ‘cutaneous adnexal carcinoma with divergent differentiation’ has been used in these circumstances.⁷⁴³ All of these tumors would now fit into a category of apocrine or sebaceous tumors.

Requena and Ackerman described a distinctive adnexal lesion with retiform and racemiform patterns.¹³⁵⁵ It showed both follicular and apocrine differentiation but differed from the sebocrine adenoma (see later).

HEMIFACIAL MIXED APPENDAGEAL TUMOR

The condition to which the name hemifacial mixed appendageal tumor was given was an erythematous papulonodular eruption confined to one side of the face of an infant.¹²⁹² It had a linear array on the cheek. The lesion was composed of islands of cells with eccrine, apocrine, and basaloid features. Similar cases in the literature, usually with comedones, have been classed as linear basal cell nevi.

MALIGNANT SWEAT GLAND TUMORS

The classification of malignant eccrine tumors is one of the most confusing areas of dermatopathology, with identical tumors reported in the literature under three or more designations. Furthermore, tumors with heterogeneous histological features that defy classification are common. Some earlier reports give scant histological details, precluding reassessment.¹³⁵⁶ It is tempting to suggest that the term ‘eccrine carcinoma’ be applied to all malignant eccrine tumors, in much the

same way that the term ‘basal cell carcinoma’ has proved adequate for a histologically diverse group of tumors.

In his major review of sweat gland carcinomas, Santa Cruz lists the synonyms and related terms used for each of the tumors he describes. He also suggests a classification based on the malignant potential as currently understood. Some of the ductal adenocarcinomas are high-grade tumors. The malignant eccrine poroma is of intermediate malignancy. The low-malignancy group includes microcystic adnexal carcinoma and eccrine epithelioma. If there is any doubt about the potential malignancy of a sweat gland tumor, aneuploidy detected by DNA image cytometry is a clear and specific indicator of prospective malignancy.¹³⁵⁷

The high frequency of positive sentinel lymph nodes in two small series of sweat gland carcinomas of different types suggests that sentinel lymph node biopsy is a useful staging tool for patients with sweat gland carcinomas.^{1358,1359} Further studies are needed to determine if this information leads to a survival benefit by selecting a group suitable for regional lymphadenectomy.¹³⁵⁹

Rarely, a pleomorphic or mixed sarcoma may arise in a sweat gland adenoma, or *de novo*, that is assumed to be derived from the myoepithelial elements of eccrine tumors. Recognition of an underlying benign tumor is usually necessary to make the diagnosis.¹³⁶⁰ The carcinosarcoma of scrotal skin reported by Lin *et al.* was composed of mucin-producing adenocarcinoma and solid spindle cell sarcoma.¹³⁶¹

There has been much interest in assessing the various immunohistochemical markers of the eccrine carcinomas. In a study of 32 cases, epithelial membrane antigen and cytokeratin were present in all cases, CEA was detected in 25, and S100 was detected in 19 cases.¹³⁶² Diffuse staining for ferritin is another marker of eccrine carcinomas.⁷⁵⁷ Whereas cutaneous metastases from internal adenocarcinomas do not usually express p63 or CK5/6, the majority of primary adnexal carcinomas (but not all apocrine carcinomas) strongly express p63 and CK5/6.^{1363–1365} D2-40, a monoclonal antibody to a component of podoplanin, which is highly expressed in lymphatic endothelium, is also a highly sensitive and specific marker that distinguishes primary skin adnexal carcinomas from adenocarcinomas metastatic to the skin.⁵¹¹ The metastatic tumors do not express podoplanin.⁵¹¹

A study of genetic and other markers in a mixed group of 21 sweat gland carcinomas found loss of heterozygosity, confined mostly to chromosome arm 17p, in four cases.¹³⁶⁶ There was only a low frequency of p53 alterations.

ADNEXAL CARCINOMAS WITH BENIGN COUNTERPARTS

POROCARCINOMA

Porocarcinoma (malignant poroma) was first described by Pinkus and Mehregan as ‘epidermotropic eccrine carcinoma’.¹³⁶⁷ Since that time, more than 200 cases have been reported; there have been four large series.^{1368–1371} The tumor occurs at all ages, although there is a predilection for older individuals. Acral locations, particularly the lower limbs, are favored.^{1371–1373} Porocarcinomas present as verrucous plaques or polypoid growths that sometimes bleed with minor trauma.^{1009,1369} Pigmented variants, due to melanocyte colonization, are uncommon.^{1374,1375}

Some are of long duration, suggesting malignant transformation of an eccrine or apocrine poroma or hidroacanthoma simplex.^{1022,1376–1378} Rarely, a porocarcinoma arises in an organoid nevus¹³³³ or a scar.¹³⁷⁹ Porocarcinomas have also arisen in a seboreic keratosis, with or without superimposed Bowenoid change.^{1380–1382} Local recurrences and metastasis, particularly to regional nodes, occur.^{1370,1383,1384} Distant metastases are less common than in some of the other malignant

counterparts of benign sweat gland tumors.¹³⁸⁵⁻¹³⁸⁸ Sometimes visceral metastases involve several organs.^{1389,1390} Cutaneous metastasis may also develop.^{1391,1392} An unusual pattern of metastasis is the development of multiple cutaneous deposits with a lymphangitic pattern and microscopic epidermotropic deposits.

In light of the distinction between apocrine and eccrine poromas, it is likely that many porocarcinomas are of apocrine origin, but further studies are needed before wholesale reclassification is done. Ultraviolet radiation and chronic immunosuppression may play a role in their induction.¹³⁹³

Treatment is with wide surgical excision with negative margins. Mohs surgery is an effective way of achieving complete removal of the lesion.¹³⁹⁴ Chemotherapy has not been effective for patients with metastatic disease.^{1395,1396} Limited success was achieved in one case with docetaxel.¹³⁹⁷ A protocol using isotretinoin and interferon- α has also been used.¹³⁹⁵ The use of radiotherapy is controversial.¹³⁹⁸

Histopathology^{1368,1369}

The intraepidermal component is composed of nests and islands of small basaloid cells, sharply demarcated from the adjacent keratinocytes.¹³⁶⁸ Broad anastomosing cords and solid columns and nests of large cells extend into the dermis to varying levels. Clear cell areas (which can be prominent in some cases),¹³⁹⁹ squamous differentiation, melanin pigment, and focal necrosis may be present in the dermal nests.^{1375,1391,1395,1400,1401} Squamous differentiation is sometimes quite extensive. Clear cell change has been found in a diabetic patient.¹⁴⁰² Ductal structures are also found (Fig. 33.66). A similar lesion, but with only an intraepidermal component, has been reported as an *in situ* porocarcinoma.^{1403,1404} This pattern must be distinguished from epidermotropic porocarcinoma, a pattern that can be seen adjacent to porocarcinomas and in cutaneous metastases.¹⁴⁰⁵ It has been said that juxtaepidermal porocarcinomas have a more aggressive behavior than dermal tumors.¹³⁹⁸ In one case, a carcinoma with features of porocarcinoma, dermal ductular carcinoma, and squamous cell carcinoma *in situ* was present.¹⁴⁰⁶ In another three cases, undifferentiated sarcomatous elements were present (**sarcomatoid porocarcinoma**).^{980,1407} One of these cases had a pseudo-angiomatous morphology, and in another there were high-grade malignant spindle cells with focal evidence of ductal differentiation.¹⁴⁰⁷ The spindle cells expressed pancytokeratin in both cases.¹⁴⁰⁷ A benign component of poroma or hidroacanthoma simplex may be present.^{924,1018,1019} An acrosyringial and ductal proliferation resembling syringofibroadenomatosis has been reported adjacent to a porocarcinoma of the heel.¹³⁷³

The cells contain variable amounts of PAS-positive material, much of which is diastase labile; prominent PAS positivity is found in clear cells.¹³⁹⁹ They stain positively for CEA, cytokeratin (pancytokeratin and CK5/6), and EMA.^{1362,1398} Estrogen receptors are sometimes present.¹⁴⁰⁸

Fine needle aspiration cytology shows clusters and sheets of round to oval cells and singly dispersed cells on a necrotic background, possessing large, round to oval nuclei with coarse chromatin and occasional nucleoli; other findings include intracytoplasmic vacuoles, occasional gland formation, and scattered mitotic figures.¹⁴⁰⁹

Electron microscopy

The tumor cells contain a variable amount of glycogen, rare tonofilaments, and intracellular lumina. The cell membranes have complex interdigitating microvilli-like cell processes. Crystalline membrane-bound granules have also been reported.¹⁴¹⁰

Differential diagnosis

Porocarcinoma can usually be distinguished from poroma by its infiltrative growth and/or cytologic atypia. However, differentiation between the two may be an issue, particularly in partial biopsies or when there

Figure 33.66 Porocarcinoma. (A) There are columns of cells with cystic change. Nests infiltrate the stroma. (B) A high-grade lesion of porocarcinoma, showing a nested pattern within the overlying epidermis and significant cytologic atypia. (H&E)

appears to be prominent mitotic activity. Porocarcinomas have a significantly higher proportion of cells expressing PCNA than do benign poromas.¹⁴¹¹ Most porocarcinomas strongly express p16, whereas poromas do not.¹⁴¹² On the other hand, both may express p53.¹⁴¹³ CK19 staining is helpful in differentiating porocarcinoma, which is usually positive for this antigen, from squamous cell carcinoma, which is usually negative or demonstrates focal staining.¹⁴¹⁴

Metastatic carcinoma from an extracutaneous site is sometimes considered in the differential diagnosis, especially in the uncommon situation in which intraepidermal growth occurs.¹⁴¹⁵ This phenomenon has been reported, for example, in metastatic prostate carcinoma. Differential staining may help in these circumstances.¹⁴¹⁶ However, it is interesting to note that prostate-specific antigen has been identified in cells of extramammary Paget disease without associated adenocarcinoma of the prostate.¹⁴¹⁷ Podoplanin, detected by the monoclonal antibody D2-40, is expressed in porocarcinomas, but not by metastatic adenocarcinomas to the skin.⁵¹¹

The variant of porocarcinoma termed malignant hidroacanthoma simplex should be distinguished from other lesions characterized by intraepidermal nesting, such as Bowen disease and seborrheic

keratosis. These lesions are positive for keratin, as is porocarcinoma, but only porocarcinoma would express CEA and/or S100 protein. Pagetoid melanoma *in situ* could also resemble intraepidermal porocarcinoma, but whereas melanoma also expresses S100 protein, the cells in question would be negative for keratin.

MALIGNANT MIXED TUMOR

Malignant mixed tumor (malignant chondroid syringoma, malignant apocrine mixed tumor) is a rare tumor of the skin most often found on the trunk and extremities, which are not the usual sites of the benign variant.¹⁴¹⁸⁻¹⁴²² Fewer than 50 cases have been reported.¹⁴²³ Sometimes, juxtaposed areas of benign and malignant tumor are found – evidence for malignant transformation of an apocrine mixed tumor, at least in some cases. Local or distant metastases are common, although there is usually a prolonged course.¹⁴²⁴ The most common site for distal metastases is the lung, followed by bone.¹⁴²³ Nodal metastases occur in more than one-third of all cases.

Early and wide surgical excision with a broad margin (3-cm clearance has been suggested) is the treatment of choice.¹⁴²³ Radiotherapy and/or chemotherapy have not been effective in diminishing the tumor mass.¹⁴²³

Histopathology

The tumors have a lobulated appearance. They are composed of an epithelial and a mesenchyme-like component, with the latter consisting of myxomatous and cartilaginous areas.^{1418,1420} The epithelial component predominates at the periphery of the tumor, where there are cords and nests of cuboidal or polygonal cells with some glandular structures. There is variable pleomorphism (Fig. 33.67). Scattered mitoses are present. Mesenchymal elements are progressively more abundant toward the center.¹⁴¹⁹ They may also be present in lymph node metastases (Fig. 33.68). Ossification is occasionally present.¹⁴¹⁸ The histological appearance may be a poor indicator of the biological behavior of a particular tumor in this category.¹⁴²⁵

The epithelial cells express cytokeratins (AE1/AE3).¹⁴²³ The luminal epithelial cells show binding to the lectin *Ulex europaeus*; intraluminal cells are CEA positive.¹⁴²⁶ Androgen receptors have not been detected.¹⁴²⁷ The chondroid areas express S100 protein.¹⁴²⁶ GFAP may also be expressed.¹⁴²³

HIDRADENOCARCINOMA (NODULAR)

Hidradenocarcinoma (malignant (nodular) hidradenoma,¹⁴²⁸ malignant acrospiroma^{1429,1430}) is a rare sweat gland tumor of the skin, which may have both apocrine and eccrine variants.^{1428,1431} Although most cases arise *de novo*, in rare cases, it may arise in a pre-existing hidradenoma.^{1428,1432} It has a predilection for the face and extremities.¹⁴³³ The trunk is sometimes involved.¹⁴²⁸ It usually presents as an ulcerated reddish nodule in older individuals, but cases have been recorded in children^{1434,1435} and at birth.¹⁴³⁶ They measure 1–5 cm in diameter; some are ulcerated.¹⁴²⁸

The tumors have an aggressive course, with eventual distant metastasis to lymph nodes, bones, and lungs.^{1430,1433,1437} In a report of seven cases from Italy, six patients died within 15–45 months of diagnosis.¹⁴²⁸ Local vascular invasion with hemorrhage caused death in three patients, whereas distant metastases occurred in a further two cases.¹⁴²⁸ Survival time was inversely proportional to the size of the tumor.

Wide local excision is the treatment of choice, with clearances of 2 cm recommended.¹⁴²⁸ Despite this, local recurrence is common. Selective lymph node dissection is often used. The value of adjuvant radiotherapy has not been confirmed.¹⁴²⁸ A case expressing *Her-2/neu*, a proto-oncogene on the long arm of chromosome 17 that encodes a tyrosine kinase receptor protein structurally related to epidermal

Figure 33.67 Malignant mixed tumor. This obviously malignant tumor shows no obvious mixed differentiation. (H&E)

Figure 33.68 Malignant mixed tumor. This deposit in a lymph node shows stromal myxoid and chondroid differentiation. (H&E)

growth factor receptor, has been successfully treated with chemotherapy and trastuzumab (Hercepten®), a humanized IgG₁ murine antibody to the extracellular portion of the Her-2/neu receptor.¹⁴³² Sweat gland tumors that express this protein are usually associated with a poor prognosis.¹⁴³² Chemotherapy is only rarely successful.

Histopathology^{1433,1436}

The tumor is composed of sheets of cells with glycogen-containing pale cytoplasm and distinct cell membranes.¹⁴³⁸ The term 'clear cell eccrine carcinoma' has been used in the past for those with a prominent clear cell component.¹⁴³⁹ In some cases, there is little clear cell change, and the cells have a basaloid or even squamoid appearance. Sometimes, squamous differentiation is widespread.¹⁴⁴⁰ Cytoplasmic vacuoles, representing intracellular lumina formation, are an important feature. Peripheral lobules of the tumors are often irregular and appear invasive.¹⁰⁸⁶ Focal necrosis is sometimes present.¹⁴⁴¹ An occasional malignant tumor is deceptively bland in appearance,¹⁴³⁶ whereas others have numerous mitoses. Melanocytes are sometimes present in the tumor lobules.

The cells express the high-molecular-weight cytokeratins CK5 and CK7, as well as p63, androgen receptor, estrogen receptor, and sometimes Her-2/neu.¹⁴³² In a larger series, all cases stained positively for keratin AE1/3 and CK5/6.¹⁴³¹ Ki-67 and p53 staining was strongly positive in five of six tumors, but the neoplasms expressed CEA, S100 protein, GCDPF-15, and EMA in no consistent pattern.¹⁴³¹

Electron microscopy

The tumor cells contain cytoplasmic glycogen and form intracellular lumina, around which tonofilaments are arranged in a circumferential pattern. Desmosomes are usually well-developed.

MALIGNANT CYLINDROMA

Malignant cylindroma is a very rare tumor of apocrine type that usually arises in a long-standing cylindroma of the scalp.^{921,923,924,1442} It develops more often in patients with multiple cylindromas.^{1443–1445} *Ab initio* variants probably also occur. This tumor has also arisen in an organoid nevus (nevus sebaceus).¹⁴⁴⁶ Multiple malignant cylindromas have been reported in a patient who also had a basal cell adenocarcinoma of minor salivary gland.¹⁴⁴⁷ The tumors are aggressive, although subsequent metastasis is rare.⁹²⁵

Wide surgical excision is the treatment of choice.

Histopathology

The tumor is composed of nests and cords of basaloid cells showing frequent mitoses, focal necrosis, and loss of the PAS-positive hyaline membrane. It has been suggested that the rare variants that have partially preserved hyaline membranes have a good prognosis.¹⁴⁴⁸ Foci of squamous differentiation occur. A contiguous benign cylindroma is usually present.¹⁴⁴⁹

MALIGNANT SPIRADENOMA (SPIRADENOCARCINOMA)

The malignant transformation of spiradenoma is a rare event, heralded by the rapid enlargement of a cutaneous nodule of long-standing.^{956,957,1450,1451} Malignant transformation appears to occur slightly more often in multiple spiradenomas than in solitary lesions.¹⁴⁵² Many different sites have been involved, with several of these tumors occurring around the elbow and on the digits.¹⁴⁵³ The trunk is the favored site.¹⁴⁵⁴ The tumors are quite aggressive, with fatal metastasis developing in at least 20% of cases. A low-grade variant with systemic metastases has also been reported.¹⁴⁵⁵

Figure 33.69 Malignant spiradenoma (spiradenocarcinoma). The lesion contains markedly atypical epithelioid to slightly fusiform cells. (H&E)

Cases have been reported of a mixed spiradenoma and cylindroma in which malignant transformation of both components occurred.¹⁴⁵⁶ The term **spiradenocylindrocarcinoma** has been proposed for this tumor.¹⁴⁵⁷ A low-grade adnexal carcinoma of the skin with glandular, trichoblastomatous, and spiradenocylindromatous differentiation has been reported – further evidence of the multidirectional differentiation that may occur in tumors of the folliculosebaceous–apocrine unit.¹⁴⁵⁸ A basaloid carcinoma of the anorectal region with spiradenocylindromatous features has been reported.¹⁴⁵⁹

Treatment is wide surgical excision. In cases with a large underlying benign (usually linear) spiradenoma, there is controversy regarding whether the benign lesion needs excision in its entirety because this may lead to mutilating surgery.¹⁴⁵²

Histopathology

There are solid islands of tumor cells, which may show either a squamous or a basaloid pattern (Fig. 33.69). Glandular and sarcomatous areas have also been reported.^{955,1460} The diagnosis depends on finding a contiguous spiradenoma because the malignant component usually lacks any distinguishing features. Sometimes, an abrupt transition between the benign and malignant components is present.¹⁴⁵⁴

The tumor cells express cytokeratins, epithelial membrane antigen,¹⁴⁵⁵ CEA, S100, and p53.^{1461,1462}

ADNEXAL CARCINOMAS WITH DISTINCTIVE FEATURES

MUCINOUS (ECCRINE) CARCINOMA

More than 150 cases of primary mucinous carcinoma of the skin have been reported.^{1463–1468} The age-standardized incidence rate is less than 0.1 per 1 million.¹⁴⁶⁹ This is a slowly growing tumor arising on the face (particularly the eyelids),^{1470–1472} scalp,^{1473–1475} axilla, and trunk of middle-aged and older individuals.¹⁴⁶⁹ The tumor nodules are often reddish and painless, measuring 0.5–7 cm in diameter. Larger variants have been recorded.¹⁴⁷⁶ Late recurrences are common. Metastases to regional nodes and widespread dissemination occur in approximately 15% of cases.¹⁴⁶³ One of the reported cases with multiple in-transit and pulmonary metastases has subsequently been challenged.^{1477,1478} Only 1

Figure 33.70 Mucinous carcinoma. A cystic and somewhat cribriform nest is present in a pool of mucin. (H&E)

case recurred, and one regional metastasis developed in the 15 cases reported from Denmark.¹⁴⁶⁹ Both an eccrine and an apocrine derivation have been suggested.^{1479,1480}

The recommended treatment varies from standard excision to wide local excision, including dissection of regional lymph nodes.¹⁴⁶⁹ Mohs micrographic surgery has also been recommended.¹⁴⁸¹ Adjuvant hormone treatment with antiestrogenic drugs for patients with estrogen receptor-positive tumors has been used. Recurrent tumors are not responsive to radiation treatment or chemotherapy.¹⁴⁶⁹

Histopathology

Mucinous carcinomas are dermal tumors that sometimes extend into the subcutis and deeper tissues. There are large pools of basophilic mucin separated by thin fibrovascular septa. Small islands of epithelial cells appear to float in these mucinous pools (Fig. 33.70). The epithelial component is denser at the periphery of the lesion. The tumor cells are small and cuboidal, and some have vacuolated cytoplasm. Rarely, signet-ring cells comprise a major component of the tumor.¹⁴⁶⁸ The cell nests in some areas have a cribriform appearance, whereas other cells form small glandular or tubular spaces containing mucin. Some of these cases originate from an *in situ* component, as seen in the corresponding mammary carcinoma.¹⁴⁶⁸ Focal neuroendocrine differentiation was present in a lesion removed from the vulva,¹⁴⁸² suggesting that it may have been an endocrine mucin-producing sweat gland carcinoma (see later). Another uncommon component may mimic infiltrating mammary carcinoma.¹⁴⁸³ A sarcomatous component was present in one case.¹³⁶¹ Epidermotropism, resembling Paget's disease, has been reported.¹⁴⁸⁴ Microcalcification is sometimes present. Psammoma bodies are rare.^{1468,1485}

The mucin is PAS positive and stains with mucicarmine and colloidal iron. It is hyaluronidase resistant and sialidase labile, indicating that it is a sialomucin. This feature assists in differentiating this tumor from a metastatic mucinous carcinoma, which it may closely mimic on histological examination.¹⁴⁸⁶ Metastatic mucinous carcinomas of intestinal origin show characteristic 'dirty necrosis'.¹⁴⁶⁸ Some mucinous carcinomas express apocrine markers.^{748,1487} MUC1 and MUC2 stain various components of the tumor.¹⁴⁶⁸ They also express low-molecular-weight cytokeratins (CK7 and CAM5.2), CEA, epithelial membrane antigen, and, sometimes, S100 protein.^{1468,1477,1487-1489} CD15 and 34BE12 are sometimes positive.¹⁴⁹⁰ There is strong nuclear expression of estrogen receptors but a more variable pattern for progesterone receptors.^{1491,1492} Focal expression of human milk fat globulin 1 (HMFG) in the luminal or outer surface of the nests is seen in one-third of all

cases.¹⁴⁹³ CK20 is not expressed, but it may be present in metastatic colorectal tumors.¹⁴⁹³ The myoepithelial cells in any *in situ* component express p63, CK5/6, calponin, smooth muscle actin, and HHF-35.¹⁴⁹⁴ Lymphatic permeation is best visualized with the D2-40 antibody.¹⁴⁹⁵

Electron microscopy

The tumor is composed of peripheral dark cells, some of which contain mucin-like material, and inner pale cells, which are less well differentiated.¹⁴⁹⁶

Differential diagnosis

Mucinous eccrine carcinoma can resemble mucinous carcinoma of breast or gastrointestinal tract, but clinical history is often decisive because metastases from these tumors do not involve the skin except in the case of obvious disseminated disease.¹⁴⁹⁷ This particular cutaneous sweat gland carcinoma does not express p63, which is frequently a means of distinguishing primary adnexal carcinomas (p63 positive) from metastatic carcinomas (p63 negative); however, p63 staining of the myoepithelial cells of sweat glands occupied by carcinoma cells may be a clue that the mucinous carcinoma is of primary cutaneous origin.¹³⁶³ A mixed tumor with abundant mucin could be confused with mucinous eccrine carcinoma, but the mesenchymal component of the former often contains fusiform stromal cells, whereas acellular mucin pools are characteristic of mucinous eccrine carcinoma.

ENDOCRINE MUCIN-PRODUCING SWEAT GLAND CARCINOMA

Endocrine mucin-producing sweat gland carcinoma is an exceedingly rare but distinctive tumor reported on the eyelids; a number of cases have been reported in approximately the past 5 years.¹⁴⁹⁸⁻¹⁵⁰⁰ It is analogous to a similar tumor reported in the breast.¹⁵⁰¹⁻¹⁵⁰⁴ There is a predisposition for elderly females.¹⁵⁰⁴ There is a multinodular, solid, and cystic dermal tumor. Some nodules contain mucin pools with adjacent areas resembling mucinous carcinoma. The cells express estrogen and progesterone receptors as well as chromogranin and synaptophysin.¹⁵⁰¹ CD57 and NSE are expressed in most cases. Also expressed are CK7, CAM5.2, and EMA.¹⁵⁰⁴

Its origin may be the apocrine glands of Moll.¹⁵⁰² However, the cases of mucinous carcinoma reported by Hanby *et al.* appeared to include both mucinous carcinomas and the lesion reported here. These authors listed tumors on the eyelids and other sites, but it is not possible from their paper to correlate site with histological pattern.¹⁴⁹¹

In the series of 12 cases reported by Zembowicz and colleagues, there were no recurrences or metastases, consistent with low-grade carcinoma.¹⁵⁰⁴

ADENOID CYSTIC CARCINOMA

More than 50 cases have now been reported with the designation 'adenoid cystic carcinoma',¹⁵⁰⁵⁻¹⁵⁰⁹ excluding purported cases in the external auditory canal.¹⁵¹⁰ In his major review, Santa Cruz appears to have accepted as adenoid cystic carcinomas all cases reported with this title. However, Cooper¹⁵¹¹ pointed out that some of these cases^{1510,1512} belong to a category of eccrine tumor that has been reported as eccrine carcinoma (eccrine epithelioma) and basal cell carcinoma with eccrine differentiation.^{1513,1514} There are rare cutaneous tumors that do have a striking resemblance to adenoid cystic carcinoma of the salivary gland, and therefore it seems appropriate to accept the existence of adenoid cystic carcinoma of the skin.¹⁵⁰⁷

The scalp and chest have been the sites of predilection.¹⁵¹⁵⁻¹⁵¹⁷ Most parts of the body have been involved, but usually only solitary cases have been reported at sites away from the scalp and chest.¹⁵¹⁸ An

exception is the vulva, where adenoid cystic carcinoma of Bartholin's gland is a recognized entity.¹⁵¹⁹ Although local recurrence is common, only a few cases with distant metastases (usually to the lung) have been reported.^{1507,1515,1516,1520} The histogenesis of these tumors has been disputed. They have been regarded in the past as eccrine tumors, although it has been acknowledged that many arise from ceruminous glands, which are modified apocrine glands. It seems best to regard these tumors as apocrine in origin.¹⁵¹⁶

Treatment is by wide surgical excision, ensuring that margins are tumor-free.¹⁵²⁰ Lymph node dissection has been carried out in a few cases. Tumors of Bartholin's gland have been treated by simple local excision and, sometimes, radical vulvectomy.¹⁵¹⁹ In the study by Ramakrishnan *et al.* (from a referral and consultation practice), among the 18 patients for which there was follow-up information, 9 had local recurrence; five of these were grade 1 and four were grade 2 or 3, according to the histologic grading system of Batsakis *et al.*^{1521,1522} Three patients developed metastatic disease and were managed by surgery, radiation therapy, and/or chemotherapy; they were still alive at 16 months to 2 years of follow-up, with no signs of active disease.¹⁵²¹ The overall 5-year survival rate for this tumor in the United States is 96%, with the best survival for tumors of the head and neck.¹⁵²³

Histopathology

The tumor is composed of islands and cords of basaloid cells showing cribriform and some tubular areas. There is abundant basophilic mucin (hyaluronic acid) in the small cysts and between cells. Mitoses are uncommon. Perineural invasion is almost invariably present.¹⁵²⁴ The histological features closely resemble those of the corresponding tumor in salivary glands.¹⁵²⁵ The tumor cells express epithelial membrane antigen and, sometimes, CEA.^{1505,1525} There is focal staining for cytokeratin, vimentin, and S100 protein.^{1516,1517,1526} Tumor cells around pseudocysts show smooth muscle actin and, in many cases, S100 staining, suggesting myoepithelial differentiation.¹⁵²¹ Type IV collagen and, to a lesser extent, laminin stain the inner luminal surface of pseudocysts. CD117 is diffusely positive.¹⁵²¹ The diagnosis can be made by fine needle aspiration cytology.¹⁵²⁷

DIGITAL PAPILLARY ADENOCARCINOMA

Digital papillary adenocarcinoma occurs as a solitary painless mass, almost exclusively on the fingers, toes, and adjacent parts of the palms and soles.^{1528,1529} Most tumors are nodular growths, less than 2 cm in diameter. More than 90% are grossly cystic.

On the basis of a review of 67 cases of this entity at the Armed Forces Institute of Pathology, the original suggestion that both a benign and a malignant form of this tumor existed was modified.¹⁵³⁰ Because none of the histological or clinical parameters studied was predictive of recurrence or metastasis, all lesions were regarded as adenocarcinomas. Metastases occurred in 14% of cases that were available for follow-up. Ackerman and colleagues call it papillary carcinoma and regard it as being of apocrine origin.⁷⁴⁶ Now that all tumors are regarded as being malignant, it seems pointless to retain the term 'aggressive' in the title, as originally used.

Treatment is by wide local surgical excision, which often results in amputation of the digit. The author has seen two cases in which the patient declined amputation only to experience a recurrence with subsequent metastases. These comments are, of course, anecdotal.

Histopathology^{850,1528,1531}

The tumor involves the dermis and subcutis; it is usually poorly circumscribed. There are tubuloalveolar and ductal structures with areas of papillary projections protruding into cystic lumina (Fig. 33.71). The ductal structures are usually larger and more dilated than those in the

Figure 33.71 (A) Digital papillary adenocarcinoma. (B) The cells lining the cystic space show papillary infolding and some atypia of cells. (H&E)

papillary eccrine adenoma. A cribriform pattern without obvious epithelial papillations is seen in approximately 20% of cases. The glandular lumina may contain eosinophilic secretory material. Scattered mitoses are present. The stroma varies from thin fibrous septa to areas of dense hyalinized collagen.

In some cases, there is poor glandular differentiation, focal necrosis, cellular atypia and pleomorphism, and invasion of soft tissues, blood vessels, and sometimes the underlying bone.^{1528,1530,1532}

Immunoperoxidase studies have shown positivity for S100 protein, CEA, and cytokeratins.¹⁵²⁸ This staining is not eccrine specific. Smooth muscle actin, calponin, p63, and podoplanin stain a myoepithelial layer around tubuloglandular structures. However, the presence of associated myoepithelial cells did not reflect benign biologic behavior in the study by Suchak *et al.*¹⁵³¹ Electron microscopy has shown eccrine glandular differentiation.

MICROCYSTIC ADNEXAL CARCINOMA

Microcystic adnexal carcinoma was first reported in 1982 by Goldstein and colleagues.¹⁵³³ It has also been referred to as malignant syringoma,¹⁵³⁴ sweat gland carcinoma with syringomatous features,¹⁵³⁵ and sclerosing sweat duct carcinoma.¹⁵³⁶ **Syringomatous adenoma of the nipple** is a closely related entity that is distinct from erosive adenomatosis (papillary adenoma) of the nipple.^{1537,1538}

Microcystic adnexal carcinoma is a slowly growing, locally aggressive tumor that presents as an indurated plaque or nodule, usually on the upper lip or elsewhere on the face.^{2,360,1539–1541} It has a predilection for the left side of the face, thought to be related to sun exposure while driving.¹⁵⁴² However, this hypothesis has not been tested because the series of 44 cases reported from Australia (where driving is on the opposite side of the road compared to that in the United States) did not have the appropriate data to allow this comparison to be made.¹⁵⁴³ It may also be found in the axilla,¹⁵⁴⁴ the extremities,¹⁵⁴⁵ genital skin,¹⁵⁴⁶ and on the trunk and scalp.^{1547–1549} It affects adults of all ages. Childhood cases are rare.^{1543,1550} It has been reported in all races, but it appears to be uncommon in African Americans.¹⁵⁵¹ In several cases, the patient has previously received radiotherapy for adolescent acne or cancers.^{1536,1549,1552–1555} Other associations have included an underlying 'systematized compound epithelial nevus',¹⁵⁵⁶ and a primary immunodeficiency syndrome.¹⁵⁵⁷

Local recurrence occurs in nearly 50% of cases,¹⁵³⁶ but this is much less likely if the excision margins are free of tumor in the initial excision.¹⁵⁵⁵ This can be achieved with Mohs micrographic surgery. The recurrence rate has been calculated as 1.98% per patient-year.¹⁵⁴² Several cases have now been reported of a high- (nuclear) grade adnexal carcinoma with features of a microcystic adnexal carcinoma that produced distant metastases.¹⁵⁵⁸ This is in addition to rare cases with lymph node involvement, almost certainly due to in-continuity extension.¹⁵³⁶ Mandibular bone marrow involvement occurred in a tumor of the mental region.¹⁵⁵⁹ Microcystic adnexal carcinoma is included within the spectrum of *locally aggressive adnexal carcinomas*.⁷⁴¹ It is regarded by many as an apocrine tumor.⁷⁴⁶

As already stated, the treatment of choice is Mohs micrographic surgical technique. If the diagnosis is made early, and if the anatomic location is accessible to excision by this technique, a favorable outcome can be expected.¹⁵⁶⁰ On the basis of several cases reported in the literature, it has been suggested that not only is radiotherapy an ineffective treatment but also this modality may induce conversion to a clinically and histologically less favorable tumor.¹⁵⁶⁰ In the series of 44 cases from Australia, treated by experienced Mohs surgeons, there was only 1 case of recurrence (5%) out of 20 patients who had completed a 5-year follow-up period after the Mohs surgery.¹⁵⁴³ Most of the cases (90.9%) in that series were on the head and neck, and 31.8% of the tumors had already recurred prior to the Mohs surgery.¹⁵⁴³

Histopathology¹⁵³⁶

The tumor usually involves the subcutis as well as the dermis, and it may extend into the underlying muscle. There is some stratification of the various histological changes. The superficial part is composed of

numerous keratinous cysts and small islands and strands of basaloid and squamous epithelium showing variable ductal differentiation. Focal clear cell change may be present in some of the cells. Rarely, this is a prominent feature.¹⁵⁶¹ Sebaceous differentiation has also been reported.^{741,1562}

The deeper component has smaller nests and strands of cells in a dense, hyalinized stroma, giving a scirrhous appearance (Fig. 33.72). Perineural invasion is frequently present.^{1563,1564} The aggressive growth and perineural spread allow a distinction to be made from syringoma and desmoplastic trichoepithelioma.

Accurate examination of frozen tissue specimens of this tumor can be a challenging task. Staining with toluidine blue may provide additional help for detecting single cells, small nests, and perineural involvement on frozen sections.¹⁵⁶⁵ Normal nerve bundles have a light blue hue, whereas nerves with tumor involvement are colored magenta.¹⁵⁶⁵

The microcystic adnexal carcinoma has become an expanding 'entity' with the inclusion of tumors that bear no relationship to those originally described. Cases of eccrine (syringoid) carcinoma are sometimes included. Notwithstanding these comments, there does appear to be a rare high-grade variant of microcystic adnexal carcinoma with marked nuclear pleomorphism and hyperchromasia, with squamous pearl formation and a widespread strong p53 immunoreaction.¹⁵⁵⁸

The **solid carcinoma**, previously included with either the eccrine (syringoid) carcinoma or the microcystic adnexal carcinoma, has been regarded as a discrete entity by Requena, Kiryu, and Ackerman.⁷⁴⁶ It consists of numerous small nests and strands of cells having a predominantly solid pattern. There is stromal desmoplasia and perineural spread.

In some of the reported cases of microcystic adnexal carcinoma, the luminal cells have been CEA positive.^{360,1350,1559} The cells stain for epithelial membrane antigen and various keratins, particularly CK7.^{1566–1568} Ber-EP4 was not expressed in any of the 13 cases studied in one series, whereas all 28 cases of basal cell carcinoma expressed this marker.¹⁵⁶⁹ Some S100-positive cells are also present.¹⁵⁷⁰ S100A6 is expressed in more than half of the cases.¹⁵⁷¹ The low level of Ki-67 supports a low proliferative rate.¹⁵⁶⁸ It has been suggested, on the basis of the electron microscopy and the immunophenotype, that microcystic adnexal carcinoma expresses both eccrine and pilar differentiation, but this is at variance with other views that it is of apocrine type.

Differential diagnosis

The differential diagnosis centers on other primary cutaneous lesions rather than metastatic tumors. These include the familiar triad of syringoma, desmoplastic trichoepithelioma, and infiltrative (morpheaform) basal cell carcinoma. On clinical grounds, microcystic adnexal carcinoma is plaque-like and ill-defined, whereas syringoma and desmoplastic trichoepithelioma are small and well circumscribed. Microscopically, both syringoma and desmoplastic trichoepithelioma are sharply demarcated, laterally and at their bases, usually extending no deeper than mid dermis, whereas microcystic adnexal carcinoma extends deeply into the subcutis. For this reason, an accurate diagnosis requires a deep biopsy. Morpheaform basal cell carcinoma displays more branching of epithelial structures than is the case for microcystic adnexal carcinoma, and clefting between tumor and stroma is a feature not observed in the latter tumor. Luminal CEA staining may help distinguish microcystic adnexal carcinoma from non-duct-forming tumors, but sometimes this marker also stains keratinized foci nonspecifically. By report, CK15 positivity separates microcystic adnexal carcinoma from infiltrative basal cell carcinoma and squamous cell carcinoma with ductal differentiation; however, CK15 and BerEp4 do not reliably separate microcystic adnexal carcinoma from desmoplastic trichoepithelioma, and therefore other methods need to be explored.¹⁵⁷² A panel including hard keratins, EMA, and CEA may be

Figure 33.72 Microcystic adnexal carcinoma. (A) Ductal structures and small cords of cells are set in a fibrous stroma. (B) Perineural invasion is present. (C) Another case. (H&E)

useful in distinguishing microcystic adnexal carcinoma from desmoplastic trichoepithelioma.¹⁵⁶⁶ The algorithm of Sellheyer *et al.* centering on staining with PHLDA1, Ber-EP4, and CK19 can be of help in addressing this particular differential diagnostic problem (see the section on differential diagnosis of desmoplastic trichoepithelioma, p. 913). The EMA positivity of microcystic adnexal carcinoma may facilitate its distinction from morpheiform basal cell carcinoma because the latter tumor is negative for EMA. Microcystic adnexal carcinoma with numerous horn cysts can resemble trichoadenoma of Nikolowski, but infiltrative cellular cords with syringoma-like profiles are not seen in the latter tumor. Although immunohistochemistry can be helpful, careful morphologic evaluation is still the gold standard for diagnosing this tumor.

OTHER SWEAT GLAND CARCINOMAS

ADENOCARCINOMA OF MOLL'S GLANDS

The glands of Moll are modified apocrine glands in the eyelids. Retention cysts (resembling apocrine cystadenoma), hidradenoma papilliferum,¹¹⁸⁶ and malignant tumors resembling apocrine adenocarcinoma have been reported.^{1121,1573} There are too few cases of adenocarcinoma in the literature for significant clinical comment.

Histopathology

The tumors resemble apocrine adenocarcinoma with architectural and cytological features of malignancy. There may be iron granules in the cytoplasm of the tumor cells. Cases reported in the past with pagetoid epidermal involvement have been regarded as possibly sebaceous rather than apocrine tumors.¹⁵⁷⁴

ADNEXAL CLEAR CELL CARCINOMA WITH COMEDONECROSIS

This recently described entity occurs in elderly individuals with a predilection for the head and neck area, especially the scalp. Tumors grow quickly, reaching a size of up to several centimeters. Follow-up has shown local recurrence in one-third of cases and regional and distant metastases in 2 of the 12 cases reported. It is composed of large tumor nests showing a distinctive zonal arrangement with the periphery of the nests formed by squamoid cells merging with centrally located clear cell areas containing foci of comedonecrosis. The lesions may show a multilobular or trabecular growth pattern and an infiltrating border. There is expression of EMA and CK17 in clear cells, with focal CEA expression in some cases. There is no ductal, cuticular, or apocrine differentiation.

APOCRINE ADENOCARCINOMA

Apocrine adenocarcinoma is a very rare tumor with no distinctive clinical features.^{1121,1157,1575} It usually presents as a single or multinodular mass, or plaque, in the axilla¹⁵⁷⁶⁻¹⁵⁷⁸ or anogenital region¹⁵⁷⁹ and rarely in other sites, such as the chest, nipple, finger,¹⁵⁸⁰ and the scalp in association with organoid nevi.¹¹⁶⁰ In one case, the tumor presented as carcinoma erysipeloides.¹⁵⁸¹ Cases arising in apocrine hyperplasia (nevus) of the axilla have been reported.^{1582,1583} Those in the anogenital region may be associated with extramammary Paget's disease.^{1584,1585} The age range in one series was 18–81 years (median, 61 years).¹⁵⁸⁶ The tumors vary from 2 to 8 cm in diameter.

Metastasis is to regional lymph nodes in the first instance, but death, usually from visceral metastases, has been reported in 40% of the

Figure 33.73 Apocrine adenocarcinoma. This is an example of ductopapillary apocrine carcinoma. There are nests of cells, some forming ducts and displaying internal papillations, with extensive infiltration of the dermis. (H&E)

reported cases.¹¹²¹ In the large series of 24 cases, 4 died with metastatic tumor (24%).¹⁵⁸⁶ There is some correlation between survival and the differentiation of the tumor.¹⁵⁷⁵

Wide surgical excision is the treatment of choice. Adjuvant radiotherapy may be beneficial in advanced cases. Chemotherapy with 5-fluorouracil, tamoxifen, and capecitabine has been used for inoperable cases.¹⁵⁸¹

Histopathology^{1121,1157}

There is great variability between tumors and even in different areas of the same tumor. Apocrine adenocarcinomas are non-encapsulated and centered on the lower dermis and subcutaneous tissue. There is a complex glandular arrangement that includes papillary, tubular, solid, and cord-like areas (Fig. 33.73). Small lumina may be present in some of the solid areas. The cells have abundant eosinophilic cytoplasm, which may be granular and sometimes partly vacuolated. Cases with signet-ring cells have been reported, but their apocrine derivation has been doubted by some authors.^{1586–1588} Some cells may show decapitation secretion, but this may be absent. There is variable nuclear pleomorphism and mitotic activity. The latter features, together with the degree of invasion, have been used to distinguish these tumors from apocrine adenomas.¹¹⁵⁸ Normal or hyperplastic apocrine glands may be seen in the vicinity; the lumen of these glands may contain foamy macrophages.¹⁵⁸⁹ A variant with a cribriform pattern has been called ‘**primary cutaneous cribriform carcinoma**’.¹⁵⁹⁰ Solid aggregations of basaloid cells have been reported.¹⁵⁹¹ Neuroendocrine differentiation was present in one case.¹⁵⁹² Pagetoid epidermal spread is uncommon in apocrine adenocarcinoma.¹⁵⁸⁶

Tumor cells have PAS-positive diastase-resistant granules in the cytoplasm; in contrast to eccrine tumors, glycogen is virtually absent. Cytoplasmic granules of hemosiderin are present in approximately one-third of cases.¹¹⁵⁷ The tumor cells express cytokeratin and GCDFP-15 but not usually CEA.^{1575,1589} S100 protein and EMA have been reported in some cases^{1575,1581} but not others.¹⁵⁷⁷ Tumor cells also express CK7.^{1578,1591} Estrogen receptors (ER) are not usually found immunohistochemically, but ER mRNA may be demonstrated by the reverse transcription PCR method in many of these negative cases.¹⁵⁹³ However, 62% of cases in one study expressed ER, and approximately the same percentage expressed androgen receptor.¹⁵⁸⁶

A tumor resembling a basal cell carcinoma but with histochemical and ultrastructural features of apocrine cells has been reported.¹⁵⁹⁴ It is best regarded as a variant of basal cell carcinoma.

EXTRAMAMMARY PAGET’S DISEASE

The precise incidence of extramammary Paget’s disease is unknown; it is rarer than mammary Paget’s disease, accounting for 6.5% of all cases of Paget’s disease.¹⁵⁹⁵ Extramammary Paget’s disease usually affects sites with a high density of apocrine glands, such as the anogenital region,^{1596,1597} and less commonly the axilla.^{1598–1601} It has also been reported in areas with modified apocrine glands, such as the external auditory canal in association with ceruminous carcinoma,¹⁶⁰² and possibly in the eyelid accompanying carcinoma of Moll’s glands. Rare sites of involvement include the glans penis,¹⁶⁰³ buttock,¹⁵⁹⁸ thigh, knee,¹⁶⁰⁴ umbilicus,¹⁶⁰⁵ abdomen,¹⁶⁰⁶ scalp,¹⁶⁰⁷ and lower anterior chest.^{1608,1609} Rare presentations have included the concurrence of mammary and vulval Paget’s disease,¹⁶¹⁰ the concurrence of genital Paget’s disease with clear cells in the epidermis of the axilla,¹⁶¹¹ its association with metastatic breast carcinoma in the arm,¹⁶¹² the presence of superimposed herpes simplex virus infection,¹⁶¹³ and the concurrent involvement of both axillae and the genital region in an elderly male.^{1614,1615} This has been called triple extramammary Paget’s disease.^{1616,1617} Extramammary Paget’s disease presented as alopecia neoplastica in one case.¹⁶⁰⁷ Paget’s disease has been reported in a supernumerary nipple¹⁶¹⁸ and also overlying a hidradenoma papilliferum.¹⁶¹⁹ Paget’s disease of the breast is sometimes quite extensive, involving a large part of the chest wall.¹⁶²⁰

Extramammary Paget’s disease presents as an erythematous, eczematoid, slowly spreading plaque. A rare pattern of erythema, localized to the underpants area, is associated with lymphatic permeation and a bad prognosis.¹⁶²¹ Rarely, the lesions may be focally depigmented.^{1622–1624} Pigmented Paget’s disease also occurs.^{1625–1628} The size of the lesion usually correlates with its duration. There is a predilection for older individuals. It has been reported in elderly siblings.^{1629,1630} There is an overall female preponderance because the vulva is a common site of involvement.^{1631,1632} Intractable pruritus is a common presenting symptom. In one study, nearly 50% of the patients had an elevated serum CEA.¹⁶³³ Genetic studies of extramammary Paget’s disease are scarce. They have not shown any consistent abnormality.¹⁶³⁴

Pathogenesis

Although it is generally accepted that mammary Paget’s disease results from the direct extension into the epidermis of an underlying intraductal adenocarcinoma in the breast,¹⁶³⁵ the histogenesis of the extramammary type remains controversial.^{1636,1637} The evidence seems to indicate that extramammary Paget’s disease does not have a uniform histogenesis.¹⁶³⁸ Approximately 25% of all cases have an underlying cutaneous adnexal carcinoma, mostly of apocrine type^{1600,1639} but sometimes derived from eccrine,^{1484,1640,1641} periurethral, perianal, or Bartholin’s glands.¹⁶⁴² The underlying appendageal component may include mucinous carcinoma or porocarcinoma. A further 10–15% of patients have an internal carcinoma involving the rectum,¹⁵⁹⁶ prostate,^{1417,1596,1643} bladder,^{1603,1631,1644,1645} cervix,^{1598,1631,1646} or urethra, which appears to be of etiological significance.¹⁶⁴² A case that possibly arose in a non-invasive rectal adenoma has been reported.¹⁶⁴⁷ Two cases have been associated with an underlying gastric adenocarcinoma.¹⁶⁴⁸ Such tumors are not always the cause of associated extramammary Paget’s disease.¹⁶⁴⁹ In the case of perianal Paget’s disease, an underlying adnexal or visceral carcinoma is present in nearly 80% of cases.¹⁶⁵⁰ Several explanations have been proposed for the pathogenesis of those cases in which no underlying carcinoma is found. They have included the presence of an underlying *in situ* adnexal carcinoma that for technical (sampling) reasons has not been discovered, or an origin from the dermal or oral

portion of sweat glands.¹⁶³¹ Alternatively, such cases could be derived from apocrine or eccrine cells or other pluripotent cells in the epidermis.^{1598,1651,1652} In the latter category are the pagetoid clear cells of the nipple, first described by Toker and thought to give rise to clear cell papulosis (see p. 795).¹⁶⁵³ They have been identified in genital skin.^{1654–1657} These cells may give rise to a primary form of Paget's disease, whereas epidermal spread of an underlying malignancy may constitute a secondary form.¹⁶⁵⁸ Because the large cells in extramammary Paget's uniformly express CK19, it has been suggested that the cell of origin might be follicular stem cells located in the hair follicle bulge region.¹⁶⁵⁹

Local recurrence of extramammary Paget's disease is quite common because of histological extension beyond the clinically abnormal area.^{1660–1662} The prognosis is generally good, except in cases with an underlying adnexal or visceral carcinoma, in which the mortality rate is 50% or higher. Reduced survival is also associated with the presence of nodules in the primary lesion, elevated CEA levels, tumor invasion level, and lymph node metastases.¹⁶⁶³ Spontaneous regression has been reported after partial surgical excision.¹⁶⁶⁴ Metastatic extramammary Paget's disease is relatively rare, although in one series it was 17%.¹⁶⁶⁵ It may spread to regional lymph nodes and visceral organs.¹⁶⁶⁵ In one case, it metastasized to a renal cell carcinoma.¹⁶⁶⁶

Treatment of extramammary Paget's disease

Wide surgical excision is the treatment of choice. There is no evidence that elective nodal dissection in the absence of palpable nodes improves survival.¹⁶⁶⁷ Other therapies include photodynamic therapy, imiquimod 5% cream,¹⁶⁶⁸ and radiotherapy.¹⁶⁶⁹ Interferon- α -2b has been used as a neoadjuvant prior to surgery.¹⁶⁷⁰ Combination chemotherapy has been used for metastatic disease.

Histopathology^{1598,1671}

The tumor cells in Paget's disease have abundant pale cytoplasm and large pleomorphic nuclei, sometimes with a prominent nucleolus (Fig. 33.74). Occasional cells have an eccentric nucleus and the appearance of a signet ring.¹⁶⁷¹ Mitoses are usually present. In early lesions, the cells are arranged singly or in small groups, sometimes with glandular formation, in the basal and parabasal regions of the epidermis. Later, the entire thickness of the epidermis may be involved, although the greatest concentration of tumor cells is in the lower epidermis.¹⁶⁷¹ They usually spread into the contiguous epithelium of hair follicles and eccrine ducts. Uncommonly, Paget cells may invade the dermis.¹⁵⁹⁸ Rarely, an invasive microacinar adenocarcinoma may develop.^{1672,1673} The epidermis is usually hyperplastic, and there is often overlying hyperkeratosis and parakeratosis. The epidermal hyperplasia has been categorized into three types – squamous hyperplasia, fibroepithelioma-like hyperplasia, and papillomatous hyperplasia.^{1674,1675} The rare pigmented form has melanocytic colonization. The dendritic cells stain for both S100 protein and HMB-45.¹⁶²³ A chronic inflammatory cell infiltrate is found in the upper dermis. An underlying *in situ* or invasive adnexal carcinoma may be present. This may show apocrine differentiation, but in other cases it is not possible to determine the cell of origin. Attempts to divide this disease into cutaneous and endodermal types on the basis of their immunohistochemical profile have already produced nonconforming cases.¹⁶⁷⁶ An unusual variant of anogenital Paget's disease has the concurrence of a dermal mucinous carcinoma and fibroepithelioma (of Pinkus)-like changes. This latter phenomenon may represent an unusual form of eccrine duct spread of the Paget's cells.¹⁴⁸⁴ Another case mimicked pemphigus vulgaris with prominent acantholysis due to scant desmosomes in the tumor cells.¹⁶⁷⁷

Metastatic Paget's disease is a rare occurrence in inguinal lymph nodes. In one case, the node contained a mixture of Paget's cells and squamoid cells, probably derived by metaplasia of the Paget's cells.¹⁶¹⁶

Figure 33.74 (A) Extramammary Paget's disease. (B) Note the pale tumor cells at all levels of the epidermis. (H&E)

Unlike the vast majority of cases of mammary Paget's disease, the tumor cells in extramammary Paget's disease contain abundant mucin, which may be confirmed by positive staining with mucicarmine, Alcian blue at pH 2.5, Hale's colloidal iron, and the PAS method (Fig. 33.75).^{1671,1678–1680} Zirconyl hematoxylin is a useful alternative for Alcian blue when it is not available.¹⁶⁸¹ However, small 'skip areas', devoid of

Figure 33.75 Extramammary Paget's disease. The neoplastic cells are well demonstrated with the PAS stain. (Periodic acid–Schiff)

mucin, have been described.¹⁶⁸² Such areas may resemble Bowen's disease.¹⁶⁵¹ The cells of clear cell papulosis (see p. 795) do not contain mucin or show cytological atypia.¹⁶⁸³ With immunoperoxidase techniques, the Paget cells stain for CEA,^{1651,1680,1684–1686} CA15.3 and KA-93,¹⁶⁸⁷ CD5,¹⁶⁸⁸ CD23,¹⁶⁸⁹ low-molecular-weight cytokeratins,^{1680,1682,1686,1690–1693} and epithelial membrane antigen.^{1651,1660,1686,1694} In one study, all 15 cases of primary extramammary Paget's disease had the cytokeratin immunophenotype CK7⁺/CK20[−], whereas only some cases secondary to underlying carcinomas were CK7⁺; furthermore, some were CK20⁺.¹⁶⁹⁵ Interestingly, CK7 is also found in Toker cells, mammary Paget cells, and Merkel cells.^{1654,1696,1697} Others have confirmed these findings.^{1632,1674,1698–1700} The Paget cells also contain apocrine epithelial antigen,¹⁶⁸⁴ MUC1, MUC2, and GCDFP, which was thought to be specific for apocrine cells.^{752,1604,1650,1700} However, GCDFP sometimes localizes in eccrine cells.^{748,1671} GCDFP is not always expressed in Paget cells. Variable staining of cells has been reported for human milk fat globulin.¹⁷⁰¹ HER-2 protein is expressed in some cases.¹⁷⁰² There is a consistent lack of estrogen and progesterone receptors, but in approximately half the cases, androgen receptors are expressed.^{1634,1703} However, they involve from only 1% of cells to more than 75% of them.¹⁷⁰⁴ Prostate-specific antigen is expressed in the pagetoid cells of many cases associated with an underlying adenocarcinoma of the prostate (Fig. 33.76).¹⁶⁴³ It may also be expressed in cases without any associated carcinoma of the prostate.¹⁷⁰³ The cells do not contain CD44 or S100 protein.^{1678,1686,1687,1692} Matrix metalloproteinases (MMP-7 and MMP-19) are often expressed in cases with an underlying carcinoma.¹⁷⁰⁵ Recently, various other proteins have been demonstrated in this condition, including insulin-like growth factor-1 receptor, p-AKT, p-ERK1/2, Stat3, Stat5a, E-cadherin, cyclin D1, and Bcl-xL.^{1706–1708} Overexpression of p53 is correlated with stromal invasion.¹⁷⁰⁹ There is also differential expression of two new members of the p53 family, p63 and p73. Overexpression of p73 occurs, whereas there is decreased expression of p63.¹⁷¹⁰

The various immunoperoxidase markers can be used to distinguish Paget's disease from Bowen's disease and superficial spreading melanoma *in situ*, should any difficulty be experienced on examining hematoxylin and eosin (H&E)-stained sections.¹⁷¹¹ Because some cases of Bowen's disease express CK7, it has been suggested that Ber-EP4 should be added to the panel of markers because it labels all cases of extramammary Paget's disease but none of the other pagetoid neoplasms.¹⁷¹² The possibility of combined Paget's disease and Bowen's

Figure 33.76 Extramammary Paget's disease. The intraepidermal tumor cells stain for prostate-specific antigen. The patient had advanced cancer of the prostate. (Immunoperoxidase stain for prostate-specific antigen)

disease should be kept in mind.^{1652,1713} Immunolabeling for syndecan-1 shows cell membrane staining in Bowen's disease, cytoplasmic expression in extramammary Paget's disease, and no expression in melanoma *in situ*.¹⁷¹⁴

Electron microscopy

There are secretory and nonsecretory cells, with the former having a prominent Golgi complex, numerous free ribosomes, and clusters of mucinous secretory granules.¹⁷¹⁵ Some cells have a few surface microvilli, and a few may border a small lumen. Adjacent Paget cells are joined by small desmosomes, and these may also exist between Paget cells and keratinocytes.¹⁶⁷¹

Differential diagnosis

The differential diagnosis includes superficial spreading (pagetoid) melanoma and pagetoid Bowen's disease. Neither melanoma cells nor the cells of squamous cell carcinoma produce mucin. The immunohistochemical profile for extramammary Paget's disease is also distinctive. Paget cells do not express S100 or HMB-45. Differential keratin staining can be used to distinguish extramammary Paget's disease from Bowen's disease: the neoplastic cells of Bowen's disease express 57- and 66-kDa keratins and not 54-kDa keratin, whereas those of extramammary Paget's disease are variable for 57-kDa keratin, negative for 66-kDa keratin, and positive for 54-kDa keratin.¹⁷¹⁶ Other markers that may help in the differentiation of extramammary Paget's disease from pagetoid Bowen's disease include syndecan-1 (membranous in cells of pagetoid Bowen's disease and cytoplasmic in extramammary Paget's disease),¹⁷¹⁴ cystic fibrosis transmembrane conductance regulator (CFTR) (positive staining favors extramammary Paget's disease),¹⁷¹⁷ and p63 (negative in primary vulvar extramammary Paget's disease; positive in Bowen's disease and in vulvar extramammary Paget's disease associated with urothelial carcinoma).^{1718,1719} Pagetoid change also occurs in sebaceous carcinoma; most often, the underlying invasive component substantiates this diagnosis, but in rare examples of primary sebaceous carcinoma confined to the epidermis, differentiation can be achieved by correlation with the clinical features and differential staining using mucins, sebaceous markers, and the characteristic markers for antigens associated with extramammary Paget's disease. Clear cell papulosis contains intraepidermal cells that are believed by some to represent precursors of mammary or extramammary Paget's disease. Mucin and immunohistochemical stains are similar in the two

situations. However, clear cell papulosis presents as whitish papules that develop along the milk lines of children. Pagetoid dyskeratosis is an incidental finding, frequently seen in polypoid lesions (skin tags) but also on the lips, hand, and in hemorrhoidal disease. These pale cells are few in number, are sometimes seen in loosely organized foci, and contain high-molecular-weight keratin.

POLYMORPHOUS SWEAT GLAND CARCINOMA

Polymorphous sweat gland carcinoma is a rare adnexal tumor characterized by a variegated histological appearance and low-grade malignant behavior.¹⁷²⁰ The lesions present as large, slow-growing dermal nodules with a marked predilection for the extremities. Local recurrence can occur, but metastasis is uncommon.¹⁷²¹

Surgical excision with conservative margins has been recommended,¹⁷²¹ but the author has seen a case with local recurrence following excision with a narrow clearance.

Histopathology

The lesions are characterized by a highly cellular proliferation with a variety of growth patterns, including solid, trabecular, tubular, pseudopapillary, and cylindromatous (Fig. 33.77). Focal small tubules

Figure 33.77 (A) Polymorphous sweat gland carcinoma. (B) An area with syringoid features is also present. (H&E)

resembling eccrine ducts are often present. The stroma may show hemorrhage and some hyalinization.¹⁷²⁰

SIGNET-RING CELL CARCINOMA OF THE EYELID

Eccrine carcinomas of the eyelid are rare and comprise three types: infiltrating ductal (syringoid) carcinoma; mucinous carcinoma, including the variant known as endocrine mucin-producing carcinoma (see p. 957);¹⁵⁰³ and a poorly differentiated tumor variously termed signet-ring, histiocytoid, or diffuse.¹⁷²² The latter tumor has also been reported in axillary skin.¹⁷²³ This tumor characteristically affects older men. It is composed of sheets and cords of polygonal eosinophilic cells, with dispersed larger, rounded single cells resembling histiocytes, and cells with cytoplasmic lumina or a signet-ring appearance.^{1722,1724} The tumor cells usually express CK7, -8, -18, and -19, human milk-fat globulin, estrogen and progesterone receptors (in some cases but not in others),¹⁷²³ and epithelial membrane antigen.¹⁷²² Staining for CEA is less strong.¹⁷²² Tumor cells have also been shown to express p63, MUC-1, Ber-EP4, and E-cadherin.¹⁷²³

SMALL CELL SWEAT GLAND CARCINOMA OF CHILDHOOD

This tumor appears to represent an unusual sweat gland anlage tumor presenting in childhood.¹⁷²⁵ It is a small blue cell tumor that needs to be distinguished from other morphologically similar tumors.¹⁷²⁵ The cells may be focally positive for AE1/AE3, CEA, and NSE.¹⁷²⁵ They do not express CK7 or -20, CAM5.2, CD99, chromogranin, CD56, or S100.¹⁷²⁵

SQUAMOID ECCRINE DUCTAL CARCINOMA

Squamoid eccrine ductal carcinoma (ductal eccrine carcinoma with squamous differentiation) is an exceedingly rare tumor that shows eccrine ductal differentiation combined with a squamoid component characterized by prominent squamous proliferation with atypia, keratinous cyst formation, and squamous eddies (Fig. 33.78).^{1726,1727} Tumors present as nodules on the head and neck or extremities.^{1726,1728} Multiple local recurrences have been recorded in one case.¹⁷²⁶

Figure 33.78 Squamoid eccrine ductal carcinoma. There are squamoid nests with focal duct formation. (H&E)

Treatment is by wide surgical excision, with or without Mohs technique. The tumor is often larger than the clinical appearance suggests.¹⁷²⁷

Histopathology

The tumor resembles an eccrine carcinoma with variable degrees of squamous differentiation and a mucinous stroma. In one case, the squamous differentiation was extensive, leading to a misdiagnosis of squamous cell carcinoma.¹⁷²⁷ This latter case expressed CD15, CEA, CK5/6, and EMA.¹⁷²⁷

SYRINGOID ECCRINE CARCINOMA

Eccrine carcinoma (syringoid carcinoma, ductal eccrine carcinoma) is a rare tumor that usually presents as a slowly growing infiltrating plaque on the scalp¹⁷²⁹ or as a plaque or nodule on the extremities or trunk.^{1513,1514,1730–1732} It has a propensity for local recurrence, but metastases are quite rare.¹⁷³³

These tumors were originally reported as basal cell tumors with eccrine differentiation (eccrine epitheliomas).¹⁵¹³ Subsequently, they have been reported as syringoid eccrine carcinomas^{1368,1734} and also as eccrine syringomatous carcinoma.¹⁷³⁵ It has been the author's practice to use this term for a group of malignant eccrine tumors composed of varying numbers of tubular structures that may be basaloid at one end of the spectrum and syringoma-like at the other end. Other components may be present (see later). Excluded from this category are tumors with morphologically specific features, such as the microcystic adnexal carcinoma (discussed previously), the adenoid cystic carcinoma, the mucinous carcinoma, and the polymorphous sweat gland carcinoma.

Treatment is wide surgical excision. In one patient with metastatic disease, chemotherapy was used, followed by maintenance tamoxifen and ibandronate.¹⁷³⁶

Histopathology

The tumor is composed of numerous tubular structures lined by one or several layers of atypical basaloid cells (Fig. 33.79).^{1513,1514,1737} Thin strands and solid nests of similar cells also occur.¹⁷³⁸ Foci with syringomatous features are often present.¹⁷³⁹ Some tumors are quite well differentiated with small ductal structures.¹⁷⁴⁰ A clear cell variant and one with possible acrosyringal differentiation have been reported.^{1741,1742} Cribriform structures have also been described.¹⁷⁴³ PAS-positive diastase-resistant material is present in the lumina of the tubular structures.

The tumor is centered on the dermis but often extends into the subcutis or deeper.¹⁷³⁹ Perineural invasion is common. Aggressive transformation has also been reported.¹⁷⁴⁴

Eccrine carcinoma differs from microcystic adnexal carcinoma by having areas with a basaloid cell pattern, in contrast to the squamoid features of the other.¹⁵¹¹ However, some eccrine carcinomas may have syringoma-like ducts (syringoid carcinoma), but these are often larger and better formed than those seen in microcystic adnexal carcinoma. Unlike the latter tumor, a desmoplastic stroma is minimal or absent in eccrine carcinoma, but cases with a sclerotic stroma have been reported.¹⁷⁴⁰

Most tumor cells express simple epithelial cytokeratins (CK7, -8, -18, and -19), and a small number express stratified epithelial cytokeratins (CK5 and -14).¹⁷⁴⁵ Apocrine markers were not expressed in

Figure 33.79 Eccrine carcinoma. It is composed of tubular structures lined by atypical basaloid cells. A few ducts have features resembling those seen in a syringoma. (H&E)

Figure 33.80 Eccrine carcinoma. This tumor has ductal structures with syringoid features. (H&E)

the two cases in which it was reported.¹⁷⁴⁵ Focal positivity for CEA¹⁷⁴⁶ and nuclear and cytoplasmic positivity for S100 have also been found.¹⁷⁴⁴

Despite the previously mentioned findings, it must be acknowledged that cases with overlap features arise (Fig. 33.80).¹⁷⁴¹ There is a growing tendency to regard this tumor as a variant of microcystic adnexal carcinoma.

INTRODUCTION

Recent immunohistochemical findings have assisted in the histogenetic classification of many of the soft tissue tumors.¹ However, because vimentin is positive in many tumors, it is of no value in the differential diagnosis of tumors discussed in this chapter.² On the other hand, the 'fibrohistiocytic' tumors are still largely enigmatic with respect to their histogenesis, and the diagnosis is largely dependent on hematoxylin and eosin (H&E) inspection.³ In addition to the 'fibrohistiocytic' tumors, this chapter includes those entities that have traditionally been grouped together on the basis of collagen production and/or the presence of fibroblasts or fibroblast-like cells forming an integral component of the tumor. It also includes tumors of presumptive origin from dermal dendrocytes and myofibroblasts.

Dermal dendrocytes

Dermal dendrocytes are bone marrow-derived cells found in different parts of the dermis.⁴⁻⁷ They are closely related to mast cells in the perivascular space.⁷ They express factor XIIIa and von Willebrand factor receptor, suggesting a possible role in tissue repair and hemostasis. An antigen-processing function has also been proposed.⁸⁻¹⁰ The subset of dendrocytes expressing factor XIIIa is found in some of the acral angiofibromas and in dermatofibromas. They are also increased in many other situations. Another subset of dendrocytes, comprising 10–30% of all interstitial cells in the reticular dermis, expresses CD34.¹¹ This antigen is expressed in vascular endothelial cells, some perivascular and interstitial dendritic cells in the dermis (as mentioned previously), and spindle cells in the basement membrane zone of eccrine ducts and the bulge area of the hair follicle. It is also expressed in a wide range of tumors.¹² The two subsets of dendrocytes appear to interact in many situations.¹³

A hamartoma composed of CD34⁺ cells has been reported as a '**dermal dendrocyte hamartoma**'.¹⁴ The cells in the three congenital lesions reported as '**medallion-like dermal dendrocyte hamartoma**' were positive for CD34, factor XIIIa, and fascin.¹⁵ Subsequent cases have been reported.^{16,17} Kutzner *et al.* concluded that this lesion is of fibroblastic rather than dendrocytic lineage, and they prefer the descriptive term 'plaque-like CD34⁺ dermal fibroma' instead of 'medallion-like dermal dendrocytic hamartoma'.¹⁸ The main differential diagnostic consideration is superficial, plaque-like dermatofibrosarcoma protuberans (DFSP). Although there are some morphologic differences, definitive differentiation can be achieved by using reverse transcriptase–polymerase chain reaction (RT-PCR) or fluorescence *in situ* hybridization (FISH) analysis, the latter being preferred for archival formalin-fixed, paraffin-embedded material (see [differential diagnosis](#) under [dermatofibrosarcoma protuberans](#), p. 1000).¹⁸

A granular cell variant of CD34⁺ cells, presenting as multiple papules and plaques in an infant, has been called '**granular cell dendrocytosis**',¹⁹ whereas a post-traumatic myxoid tumor of the thumb composed of both CD34⁺ and factor XIIIa⁺ cells has been called a '**myxoid dermatofibrohistiocytoma**'.²⁰ Yet another term, '**CD34⁺ eruptive fibroma**', has been used for the multiple papules composed of CD34⁺ spindle cells reported on the neck and upper chest of a female teenager.²¹ The term '**CD34-reactive myxoid dermal dendrocytoma**' was used for another unique case.²² Some CD34⁺ dermal proliferations defy classification.²³ One such case had perivascular spindle cells that formed a dermal 'fibroma'.²⁴ There is much to be said in favor of a simple diagnosis of 'CD34⁺ dendrocytoma' for all these variants.

Myofibroblasts

Tumors of myofibroblasts are also considered in this chapter. They often coexist with ordinary fibroblasts in many of the lesions. There is still a lack of consensus regarding their exact role in the formation

of the soft tissue tumors usually attributed to them.³ It has even been suggested that myofibroblasts are merely a functional stage of fibroblasts, smooth muscle cells, or pericytes, and that their identification requires the ultrastructural recognition of the so-called 'fibroneexus' (microtendons).^{25,26} In addition to an origin from fibroblasts, myofibroblasts have been derived experimentally from microvascular endothelial cells by the action of inflammatory cytokines.²⁷ Neoplastic myofibroblasts express vimentin, muscle actin, α -smooth muscle actin, and/or desmin, although the specificity of desmin has been questioned. Myofibroblasts are best defined ultrastructurally because their immunohistochemical profile is not specific.²⁸

Various attempts have been made to simplify this difficult subject, including an algorithmic approach based on colors^{29,30} and the application of molecular genetics.³¹

ACRAL ANGIOFIBROMAS

Acral angiofibromas are a clinically diverse group of entities that share distinctive histological features.^{32,33} They are thought by some to represent hyperplasias of the papillary and/or periadnexal dermis (the adventitial dermis).³⁴ Immunohistochemical studies have shown that the large stellate fibroblast-like cells that characterize these tumors express factor XIIIa.^{35,36} They are not mesenchymally derived fibroblasts.³⁷ Factor XIIIa appears to be important in the promulgation of fibroplasia.³⁸

Tumors derived from the perifollicular mesenchyme – the perifollicular fibroma, trichodiscoma, and fibrofolliculoma – are usually considered separately from the acral angiofibromas.³⁹ They are discussed with the tumors of the hair follicle (see p. 920).

The following clinical conditions are discussed:

- Adenoma sebaceum (tuberous sclerosis)
- Angiofibromas in other syndromes
- Fibrous papule of the face
- Pearly penile papules
- Acral fibrokeratoma
- Familial myxovascular fibroma.

The entity reported as linear papular ectodermal–mesodermal hamartoma has some features of this group.⁴⁰

ADENOMA SEBACEUM

'Adenoma sebaceum' is the misnomer (there is no adenomatous proliferation of sebaceous glands as the name implies) used for the angiofibromatous lesions found in most patients with tuberous sclerosis (OMIM 191100), an autosomal dominant neurocutaneous syndrome in which learning disability and epilepsy are often present.^{41,42} Major reviews of the tuberous sclerosis complex have been published in recent years.^{43,44} Other organ systems are often involved.^{43,45,46} Other cutaneous angiofibromatous lesions may accompany adenoma sebaceum, and these include plaque-like lesions of the forehead and scalp and ungual fibromas (see acral fibrokeratomas on p. 971).⁴⁷⁻⁴⁹ 'Shagreen patches', with the histology of connective tissue nevi, are commonly found in tuberous sclerosis.⁵⁰ They are usually present by puberty.⁵¹ Hypopigmented macules are a common finding.⁵² Molluscum pendulum is less common.⁵³ Oral fibromas, mostly gingival in location, and dental pits are common findings in the mouth.⁵⁴ Genetic linkage studies initially indicated that approximately half of all families with tuberous sclerosis showed linkage to chromosome 9q34 (*TSC1*) and the remainder to chromosome 16p13 (*TSC2*).^{55,56} Subsequent studies have shown that *TSC1* mutations account for only 10–30% of the families identified with tuberous sclerosis complex. In sporadic cases, there is an even greater excess of mutations in *TSC2*. This latter

group is usually associated with more severe disease.⁴³ No identifiable mutations can be found in 15–20% of patients meeting the clinical criteria of tuberous sclerosis.⁴³ Hamartin is encoded by *TSC1*, and tuberlin, a tumor suppressor, is encoded by *TSC2*. There is a wide spectrum of mutations. More than 200 *TSC1* and nearly 700 *TSC2* unique allelic variants have been reported.⁴³ Approximately two-thirds of all cases are sporadic and assumed to result from new mutations, many of which are in *TSC2*.⁵⁷ Other cases are inherited as an autosomal dominant trait. Mutation screening in tuberous sclerosis is labor-intensive and expensive.⁵⁸ It is now available commercially. Prenatal or preimplantation genetic testing is becoming more widely available.⁴³ A study of cultured fibroblasts from cutaneous tumors of patients with tuberous sclerosis demonstrated second-hit mutations of *TSC2* of the CC>TT type, which are considered ‘ultraviolet signature’ mutations; this suggests that restriction of ultraviolet exposure in children with tuberous sclerosis might reduce the number and severity of facial angiofibromas.⁵⁹

Adenoma sebaceum consists of several or multiple papules and nodules, sometimes grouped, with a predilection for the butterfly area of the face, particularly the nasolabial groove.^{45,47} They appear in early childhood as pink-red to yellow-brown lesions, and their growth is usually progressive until adult life. A giant angiofibromatous plaque and a cluster growth of large nodules⁶⁰ have been reported. Unilateral facial involvement is another clinical variant.⁶¹ It probably represents mosaicism.^{62–66}

Facial angiofibromas in tuberous sclerosis have been treated with a scanning carbon dioxide laser.⁶⁷ The benefits of therapy should be weighed against both early morbidity and the risks of long-term complications such as scarring and hypopigmentation.⁶⁷ Erbium lasers have also been used. Clinical trials using sirolimus (rapamycin), an mTOR inhibitor, have shown promise.^{44,68} mTOR has a central role in the control of cell growth and proliferation.^{69,70} Its activation is influenced by heterodimers of *TSC1* and *TSC2*.⁴³ Topical treatment with a rapamycin–tacrolimus ointment resulted in significant improvement of these skin lesions.⁷¹ It has been suggested that long-term therapy with sirolimus may increase the risk of malignant tumors in these patients.⁴³ The finding of increased levels of certain matrix metalloproteinases (MMPs) in lesional skin raises the possibility of antiprotease treatments in the future or the use of retinoids, which inhibit the production of MMPs.⁷²

Histopathology^{33,73}

The lesions vary from rounded elevations to raised pedunculated growths (Fig. 34.1).⁷³ The epidermis shows some flattening of rete ridges with patchy melanocytic hyperplasia and also mild overlying hyperkeratosis. The dermal component consists of a network of collagen fibers, often oriented perpendicular to the surface in the subepidermal zone and having an onion-skin arrangement around follicles and sometimes blood vessels (Fig. 34.2). There is an increase in ‘fibroblastic’ cells, which are plump, spindle shaped, stellate, or even multinucleate. There is often a sparse inflammatory infiltrate that includes mast cells. The blood vessels are increased in number, and some are dilated with an irregular outline.⁷⁴ It has been suggested that a functional loss of tuberlin may stimulate vascular growth.⁷⁵ Sporadic angiofibromas do not show loss of tuberlin or hamartin.⁷⁶ Follicles may show epithelial proliferation, and there may be primitive small follicles.⁷⁷ Elastic tissue is absent from the stromal fibrous tissue. The extracellular glycoproteins fibronectin and tenascin are increased in the stroma.⁷⁸ There is also overexpression of *MLH-1* and *psoriasin* genes in the cutaneous hamartomas.⁷⁹ Staining for CD31 confirms the increased vascularity of these lesions.

Electron microscopy

Ultrastructural examination⁸⁰ has shown large numbers of microvilli on the luminal surface of the endothelial cells of the vessels. The

Figure 34.1 Adenoma sebaceum. There are pedunculated outgrowths with an angiofibromatous stroma. (H&E)

Figure 34.2 Adenoma sebaceum. Collagen is arranged around the small blood vessels in the upper dermis. Fibroblasts are increased in number, but they are not as stellate as usual. (H&E)

stroma contains many banded structures. No myofibroblasts have been seen.

ANGIOFIBROMAS IN OTHER SYNDROMES

Facial angiofibromas, both unilateral and bilateral, have already been mentioned as an important manifestation of tuberous sclerosis. They have also been described in a patient with *neurofibromatosis 2* (NF-2; OMIM 101000) as a cluster of small papules on the ear.⁸¹ Multiple facial angiofibromas are seen quite often in patients with *multiple endocrine neoplasia* (MEN) type 1 (OMIM 131100).⁸² They tend to present in adult life.⁸³ Other cutaneous tumors in this syndrome include collagenomas and lipomas.⁸⁴ There may also be café-au-lait macules and confetti-like hypopigmented macules.⁸⁵ The tumors show allelic deletion of the *MEN1* gene. It encodes a protein called menin, which is presumed to act as a tumor suppressor. Basic fibroblast growth factor is elevated in many patients and may be responsible for the formation of the cutaneous tumors.⁸³

Angiofibromas (often reported as perifollicular fibromas) have been reported in the *Hornstein–Knickenberg syndrome*, which appears to be

a slightly different phenotypic expression of the Birt–Hogg–Dubé syndrome (see p. 920). Multiple facial angiofibromas have also been reported in the *Birt–Hogg–Dubé syndrome* (OMIM 135150).⁸⁶

Multiple eruptive angiofibromas of the trunk have been reported in the absence of any underlying disease state.⁸⁷ Unilateral facial angiofibromas were present in a teenage male, with no signs of a systemic syndrome.⁸⁸

FIBROUS PAPULE OF THE FACE

Fibrous papules of the face are usually solitary, dome-shaped papules, measuring 3–5 mm in diameter, found particularly on the nose of middle-aged adults.^{33,89,90} They are flesh colored and usually asymptomatic, although some may bleed after minor trauma. They were originally regarded as fibrosed dermal nevi,^{89–91} a proposition that has been disproved by electron microscopy^{92,93} and immunohistochemistry.^{94–96} The presence of factor XIIIa in the spindle cells and in some stellate cells suggests that fibrous papule is a proliferative reactive process consisting mainly of dermal dendritic cells.^{95,96}

Histopathology^{33,73,89,90}

The changes are similar to those described for adenoma sebaceum. However, the vessels are sometimes more ectatic and less likely to show concentric fibrosis than in adenoma sebaceum (Fig. 34.3). Furthermore, the bizarre cells in the dermis are usually more numerous and the basal melanocytic hyperplasia more prominent in fibrous papule of the face. Rarely, the stromal cells may contain coarse cytoplasmic granules leading to a *granular-cell* appearance.⁹⁷ Another rare pattern involves the presence of numerous fibroblasts/histiocytes/dendrocytes with clear vacuolated cytoplasm embedded in a dense sclerotic and hyalinized stroma.⁹⁸ A few multinucleate ‘floret’-like cells may be present. Only a few cells stain for factor XIIIa and CD68. This lesion, *clear cell fibrous papule*, may eventually prove to be unrelated to fibrous papule, although the cases reported were all on the face, predominantly the nose (Fig. 34.4).⁹⁹ Other rare variants include *hypercellular*, *pigmented*, *pleomorphic*, *inflammatory*, and *epithelioid* fibrous papules.¹⁰⁰ The morphologic features of isolated oral fibromas of the tongue closely resemble those of fibrous papule, and as is the case for many fibrous papules, these lesions tend to lack concentric fibrosis around vessels.¹⁰¹

The spindle and stellate cells in fibrous papule of the face contain vimentin and factor XIIIa (discussed previously) but not S100 protein.^{95,102,103} α_1 -Antitrypsin and lysozyme were detected in one study, although this has not been confirmed subsequently.¹⁰⁴ A case with CD34⁺ cells has been reported.¹⁰⁵ The cells of the epithelioid fibrous papule are reactive for procollagen and are negative for NKI/C3, unlike previously described clear cell variants.^{106,107}

Electron microscopy

Ultrastructural studies suggest that the stellate cells are fibroblastic or fibrohistiocytic.^{92,93}

PEARLY PENILE PAPULES

Pearly penile papules are persistent asymptomatic pearly white papules, 1–3 mm in diameter, occurring in groups or rows on the coronal margin and sulcus of the penis.^{32,108–111} Rarely, they may be found on the penile shaft¹¹² or glans.¹¹³ They are found in 10–30% of young adult males, and they are more common in black people and in the uncircumcised.^{109,114} They may be misdiagnosed as warts,¹¹⁰ but there is no causative role for human papillomavirus (HPV) in their genesis.¹¹⁵

Treatment with cryotherapy has been effective in some studies but not in all.¹¹⁴ Carbon dioxide laser has also proved effective.¹¹⁴

Figure 34.4 Clear cell fibrous papule. This lesion from the nasal ala contains telangiectatic vessels and sheets of clear cells. (H&E)

Figure 34.5 Pearly penile papules. Scattered fibroblast-like cells are present within the dermis, together with dilated vessels – several of which can be seen at the base of the biopsy specimen. (H&E)

Histopathology³²

There is a rich vascular network, surrounded by dense connective tissue containing an increased number of plump and stellate ‘fibroblasts’ (Fig. 34.5). They resemble other lesions in this group, except for the absence of pilosebaceous follicles.

ACRAL FIBROKERATOMA

Included in the acral fibrokeratoma group¹¹⁶ are lesions reported as acquired digital fibrokeratoma,^{117–120} acquired periungual fibrokeratoma, ‘garlic clove fibroma’,¹²¹ and the subungual and periungual fibromas of tuberous sclerosis.⁴⁷ This unifying concept is an attempt to overcome the needless proliferation of terms, and it gives recognition not only to the common histopathological features but also to the fact that occasional lesions have been reported in sites other than digits.¹²²

The lesions are usually solitary, dome-shaped, or elongated thin horns, 1–3 mm in diameter and up to 15 mm in height.⁴⁹ A giant variant measuring almost 4 cm in diameter has been reported.¹²³ There is sometimes a history of trauma.¹¹⁸ The ungual fibromas of tuberous

Figure 34.6 Acral fibrokeratoma. This lesion, which was clinically horn-like, has a core of fibrous tissue and an epidermal covering with overlying orthokeratosis. Dilated vessels are present at the tip. (H&E)

sclerosis are often multiple, sometimes in clusters, and develop around the time of puberty.¹²⁴ They are found in approximately half the patients with tuberous sclerosis.^{42,47}

Some fibrokeratomas originate from the dermal connective tissue, whereas others appear to originate from the proximal nail fold.¹²⁵ An invaginated variant has been reported in relation to the nail apparatus.¹²⁶ This difference in the site of origin may account for the heterogeneous features observed in this entity.

Multiple acral fibromas with a myxoid but poorly vascularized stroma have been reported in a patient with familial retinoblastoma, leading to the suggestion that multiple acral benign tumors with a fibrous component might be a cutaneous marker of tumor suppressor gene germline mutation.¹²⁷ Lesions reported as **familial multiple acral mucinous fibrokeratomas**¹²⁸ and familial myxovascular fibroma (see later) are probably further examples of this hypothesis.

Histopathology

The epidermal covering usually shows hyperkeratosis and sometimes acanthosis. There is a core of thick collagen bundles that are oriented predominantly in the vertical axis (Fig. 34.6). Stellate fibroblasts are

often present. There is sometimes prominent cellularity¹²⁵ and a rich vascular supply. These latter two features have not been prominent¹¹⁹ or have been specifically excluded¹²⁹ in some of the reports, suggesting that some of the lesions might best be regarded as fibromas^{116,127} rather than angiofibromas. The rare invaginated variant is characterized by a deep epithelial invagination proximal to the normal matrix.¹²⁶ A pseudo-nail plate is produced.

There are usually sparse elastic fibers, few inflammatory cells, and no hair follicles. Neural tissue is not present, unlike the clinically similar entity of supernumerary (rudimentary) digits.^{119,130} The stromal cells express varying amounts of factor XIIIa.

The **cellular digital fibroma** is composed of intersecting fascicles of thin, delicate spindle cells in the superficial reticular dermis with a fibrotic and slightly myxoid stroma.¹³¹ It may be histogenetically distinct from other angiofibromas and digital fibrokeratomas because the constituent cells in cellular digital fibromas stain strongly for CD34, with only scattered stromal cells expressing factor XIIIa.¹³¹ This entity needs to be distinguished from DFSP. It has been suggested subsequently that cellular digital fibroma is a variant of, if not the same as, superficial acral fibromyxoma (see p. 1012).¹³²

On dermoscopy, acral fibrokeratoma shows a white, scaly collarette, peripheral to which is a zone of erythema with globular vessels.¹³³

FAMILIAL MYXOVASCULAR FIBROMA

Three kindreds have been reported in which multiple verrucous papules developed on the fingers and hands.^{128,134,135} On histological examination, the papules showed a fibrovascular proliferation of the papillary dermis, with variable myxoid change and overlying epidermal acanthosis and hyperkeratosis.

Differential diagnosis

Larger examples of angiofibroma have features in common with connective tissue nevi, and these may in fact be closely related entities. As noted previously, a major differential diagnostic consideration is the supernumerary digit (rudimentary polydactyly), which can closely resemble digital fibrokeratoma clinically. However, supernumerary digits characteristically occur at the base of the fifth finger, are present at birth, may be bilateral, and show prominent nerve bundles in the deep dermis, with a configuration comparable to neuromas of other types. These are in fact believed to occur as the result of autoamputation of a true accessory digit. As supporting evidence of this concept, the editor has seen an example of an accessory digit, to which was attached a neuroma with features of a small supernumerary digit. The connective tissue changes of onychomatricoma can resemble those of fibrokeratoma of the nail bed, especially if the nail plate has been removed. A distinction can be made by recognizing in onychomatricomas the characteristic epithelial-lined invaginations surrounding optically empty cavities – negative images of the keratogenous zones that comprise the ungual spurs on the inferior border of the involved nail plate.¹³⁶ There is some overlap of familial myxovascular fibroma with the lesions included within the concept of cutaneous myxomas (see p. 1012).

FIBROUS OVERGROWTHS, FIBROMATOSES, MYOFIBROBLASTIC PROLIFERATIONS, AND FIBROSARCOMA

This heterogeneous group of lesions forms a histological spectrum, at one end of which is the fibroma and at the other end the fibrosarcoma.

In between are the ‘fibromatoses’, which have been defined as a “group of nonmetastasizing fibrous tumors which tend to invade locally and recur after surgical excision.”¹³⁷

The ‘fibromatoses’ include entities such as palmar and plantar fibromatosis,¹³⁸ extra-abdominal desmoid,^{139,140} knuckle pads, pachydermodactyly, Peyronie’s disease of the penis, and various ‘juvenile fibromatoses’ such as juvenile aponeurotic fibroma, fibrous hamartoma of infancy, digital fibromatosis of childhood, and infantile myofibromatosis. The tumors in this latter category usually contain an admixture of fibroblasts and myofibroblasts. This is the explanation for their inclusion also as tumors of myofibroblasts (see later).

Plantar fibromatosis is a benign, but sometimes locally aggressive, proliferation of fibrous tissue involving the deep subcutis and fascia of the plantar surface of the foot. Familial cases occur.¹⁴¹ In a study, from the Armed Forces Institute of Pathology (AFIP), of 56 cases of palmar-plantar fibromatosis in children and preadolescents, there was a high incidence of local recurrence of their fibromatosis.¹⁴² Most cases had been initially managed by local excision, and in most cases, there were positive margins.¹⁴² Most cases of plantar fibromatosis contain multinucleated giant cells, but the number of these cells is quite variable.¹⁴³ They also occur in palmar fibromatosis.¹⁴⁴ A variant with distinct nodules occurs.^{138,142} *Peyronie’s disease* of the penis, nodular and diffuse fibrous proliferations of the penis and tunica vaginalis,¹⁴⁵ and *Dupuytren’s disease* of the palmar fascia are similar fibromatoses.¹⁴⁶ There is a high incidence of chronic liver disease in patients with Dupuytren’s disease.¹⁴⁷ The *desmoid tumor* (a clonal process) and *extra-abdominal desmoid tumor* are usually regarded as belonging to the domain of soft tissue tumors.^{148–158} They are not considered further. Platelet-derived growth factor (PDGF) receptors and ligands are upregulated in fibromatoses; they may play a role in the growth of these tumors.¹⁵⁹ The nuchal fibroma (see p. 369)¹⁶⁰ and the nuchal fibrocartilaginous tumor (see p. 431)¹⁶¹ are considered elsewhere. The nuchal-type fibromas that arise in association with colonic polyps may be multiple and occur in different locations.¹⁶² They have been called **Gardner fibromas**. They are discussed later in this chapter (see p. 974).

Tumors of myofibroblasts include nodular fasciitis, fibrous hamartoma of infancy, digital fibromatosis of childhood, postoperative spindle cell nodule, dermatomyofibroma, infantile myofibromatosis, inflammatory myofibroblastic tumor, plexiform fibrohistiocytic tumor, and myofibroblastic sarcoma. Partial myofibroblastic differentiation is seen in low-grade fibromyxoid sarcoma and angiomyofibroblastoma of the vulva. Plexiform fibrohistiocytic tumor is considered with the fibrohistiocytic tumors (see p. 996) because of the dual population of cells. Congenital-infantile fibrosarcoma is usually included as a myofibroblastic lesion.^{25,28} The case with myofibroblastic proliferation confined to the skin of the neck defies classification.¹⁶³

Electron microscopy is of some value in distinguishing between the various spindle cell tumors of the skin and soft tissues.¹⁶⁴ Cytogenetic analysis of tumors adds further information; some tumors have specific karyotypic aberrations.¹⁶⁵

SKIN TAGS

Skin tags (soft fibromas, acrochordons, fibrolipomas, fibroepithelial polyps) are common cutaneous lesions that have received little attention in the dermatological literature because hitherto they have been regarded as being of little consequence. However, there have been several reports suggesting an association between the presence of skin tags and underlying diabetes,^{166–170} abnormal lipid profile,¹⁷¹ colonic polyps,^{172–175} or acromegaly.¹⁷⁶ The association with colonic polyps is controversial, and several studies have failed to confirm its existence.^{177–179} HPV types 6/11 were detected in a significant number of cases in one study.¹⁸⁰ This finding remains to be confirmed.

Skin tags have a predilection for the axilla, neck, groin, eyelids, and beneath pendulous breasts. They are more common in obese females, and they may develop in pregnancy.¹⁸¹ In one autopsy study, they were present in 64% of individuals older than the age of 50 years,¹⁷⁷ whereas in a more recent study they were present in 46% of 750 individuals examined.¹⁸² There are three clinical types:¹⁷⁷ furrowed papules approximately 2 mm in width and height; filiform lesions, approximately 2 mm in width and 5 mm in height; and large bag-like protuberances, usually on the lower trunk.^{183,184} These larger lesions are very occasionally multiple.^{166,185} The term fibroepithelial polyp is sometimes used for this latter variant. Experimentally, these polyps show downregulation or loss of tuberin and/or hamartin expression that may promote collagen formation, leading to their formation and growth.¹⁸⁶

Vestibular papillae of the vulva are skin tag-like smooth projections of the vestibular mucosa that appear to be normal anatomical variants.^{187,188} They are not related to HPV infection, as previously suggested.¹⁸⁷⁻¹⁸⁹

Fibroepithelial polyps of the anus are relatively common lesions, some of which are thought to arise from enlargement of anal papillae.¹⁹⁰ They should be distinguished from the much smaller **infantile perianal (perineal) pyramidal protrusion**, which occurs predominantly in young girls in the midline, anterior to the anus.¹⁹¹⁻¹⁹³ Sometimes they are posterior to the anus.¹⁹⁴ Underlying constipation and anal fissures are often present.¹⁹⁴ A variant associated with lichen sclerosus may also occur.^{194,195} They are edematous, flesh-colored, sessile protrusions measuring 1 or 2 cm in length. They should not be mistaken for condylomas.¹⁹⁶ One case has been successfully treated with topical steroid applications.¹⁹⁷

The **lymphedematous fibroepithelial polyp of the penis** is a rare polyp of the glans penis or prepuce associated with long-term condom catheter use.¹⁹⁸ On rare occasions, it has been associated with chronic phimosis.¹⁹⁹ The lesions are gray-white polyps measuring 2–7.5 cm in diameter.¹⁹⁸ The majority of lesions affect the ventral surface of the glans near the urethral meatus. It has been postulated that the lesions represent a reactive hyperplastic process involving the subepithelial stroma.¹⁹⁹ A related lesion is the polyp of the glans penis that developed in a man who practiced genital hanging kung fu.²⁰⁰

The histological features vary with the clinical type. The furrowed papules show epidermal hyperplasia and sometimes horn cyst formation. These lesions, with seborrheic keratosis-like surface changes, are most common on the neck and eyelids (Fig. 34.7A).²⁰¹ The filiform lesions are covered by an epidermis that shows only mild acanthosis. Pagetoid dyskeratosis (see p. 311) is sometimes an incidental finding in the overlying epidermis.²⁰² The connective tissue stalk is usually composed of well-vascularized, loosely arranged collagen. Elastic fibers are present in normal amounts.²⁰³ A few fat cells and, sometimes, nevus cells may be present. The larger, bag-like lesions (fibroepithelial polyps, fibrolipomas) usually have a stroma composed of loosely arranged collagen and a central core of adipose tissue (Fig. 34.7B). It has been suggested, and subsequently challenged, that there is little utility in submitting these lesions for histological examination.^{204,205}

Vestibular papillae of the vulva consist of connective tissue projections covered by stratified squamous epithelium.¹⁸⁷ Sometimes the epithelium is glycogen rich, simulating koilocytes.¹⁸⁸

An unusual cutaneous polyp with bizarre stromal cells, thought to represent a degenerative phenomenon, has been reported as a '**pseudosarcomatous polyp**'.²⁰⁶ Subsequent correspondence raised the possibility that the lesion may have been a dermal spindle cell lipoma or 'ancient' (degenerative) change in a polyp.²⁰⁷

The **fibroepithelial polyp of the anus** has a myxoid and/or collagenous stroma covered by stratified squamous epithelium that may show some swollen cells with vacuolation near the surface.²⁰⁸ The stroma sometimes contains atypical cells showing fibroblastic and myofibroblastic differentiation.¹⁹⁰ Hyalinized vascular changes may be present near the base of the polyps.²⁰⁹ There is an increase in CD34⁺ stromal

Figure 34.7 Skin tag. (A) This furrowed lesion shows papillomatosis with a somewhat seborrheic keratosis-like surface. (H&E) (B) This plump lesion features loosely arranged collagen and a central zone composed of adipose tissue. (H&E)

cells.²⁰⁹ The **infantile perianal pyramidal protrusion** reveals epidermal acanthosis, marked edema in the upper dermis, and a mild inflammatory cell infiltrate.¹⁹¹

The **lymphedematous fibroepithelial polyp of the penis** has a polypoid configuration covered by keratinizing squamous epithelium. The stroma is edematous with dilated vessels and focal proliferation of

capillary-sized vessels with hyalinization. The focally myxoid stroma contains small spindle-shaped cells with ill-defined, pale eosinophilic cytoplasm. There are abundant bizarre multinucleated giant cells. A mild infiltrate of lymphocytes, plasma cells, and mast cells is present in the stroma.¹⁹⁹

Differential diagnosis

Other types of lesions can arise within, or have clinical features of, fibroepithelial polyps, including basal cell carcinomas or cutaneous pseudosarcomatous polyps. Polypoid melanomas also exist, although lesions tend to be larger than the average fibroepithelial polyp; these can be amelanotic. The ‘acrochodrons’ of Birt–Hogg–Dubé syndrome usually show evidence of fibrofolliculoma or trichodiscoma when lesions are appropriately oriented and sectioned. There are two recent cases of well-differentiated liposarcomas that presented clinically as skin tags; diagnosis was supported by FISH analysis, showing amplification of murine double-minute type 2 (*MDM2*) gene and the cyclin-dependent kinase-4 (*CDK4*) gene.²¹⁰ Findings such as these, although uncommon, support the argument that at least some fibroepithelial polyps, particularly those with unusual clinical features, should be submitted for histopathologic study.

PREPUBERTAL VULVAL FIBROMA (ASYMMETRIC LABIUM MAJUS ENLARGEMENT)

Prepubertal vulval fibroma was the term used by Iwasa and Fletcher in 2004 for a hitherto unrecognized mesenchymal tumor of the vulva in 11 prepubertal girls.²¹¹ These authors regarded them as tumors on the basis of recurrences in several cases after excision. The following year, Vargas and colleagues reported 14 cases, also from Boston, of a similar lesion that presented with enlargement of one, or occasionally both, labia majora. On the basis of its occurrence at an age roughly coincident with the time of breast budding, its capacity for spontaneous regression, and its composition of elements native to the vulva, the authors concluded that the entity represented an asymmetric physiological enlargement in response to hormonal surges of pre- and early puberty.²¹²

The girls were aged 4–13 years. The lesions were ill-defined and consisted of fibro-fatty tissue ranging in size from 2 to 8 cm in greatest dimension.^{211,212} As previously mentioned, several cases recurred after initial excision.

Histopathology

The tumors were poorly margined, hypocellular masses in the dermis and subcutaneous tissue. They were composed of the usual constituents of vulvar soft tissue, with expansion of the fibrous component.²¹² There were bland spindle-shaped cells in a variably collagenous to edematous or myxoid stroma.²¹¹ The interconnected fibrous bands encircled lobules of fat, blood vessels, and nerves.²¹² The fibroblastic cells were immunoreactive for CD34;²¹¹ they also expressed estrogen and progesterone receptors.²¹²

GARDNER FIBROMA

Gardner fibroma is a benign lesion of the superficial and deep soft tissues, presenting most commonly in childhood and adolescence with an association with familial adenomatous polyposis and desmoid fibromatosis.^{162,213} Sporadic cases also occur. The majority of cases involve the back and paraspinal region, followed by the head and neck, and the extremities. Almost 20% of patients have concurrent or subsequent desmoid tumors.²¹³ There is a strong association with familial adenomatous polyposis or adenomatous polyposis coli, but the proportion of sporadic cases that have the *APC* mutation remains to be

elucidated.²¹³ The Gardner fibroma can be the presenting feature of familial adenomatous polyposis.²¹⁴

There are some overlap features with nuchal fibroma (see p. 369), but the predilection of nuchal fibroma for middle-aged males, its location on the posterior neck, and its association in some patients with diabetes mellitus – but not familial adenomatous polyposis – usually allows a distinction to be made.

Histopathology

There is a bland, hypocellular proliferation of haphazardly arranged coarse collagen fibers with inconspicuous spindle cells.²¹³ There are small blood vessels and a sparse mast cell infiltrate. The collagen forms around adipose tissue lobules. There is no increase in small nerve bundles, as seen in nuchal-type fibroma (see p. 369).

In one study, 64% of cases tested showed nuclear reactivity for β -catenin, and 100% of cases showed nuclear reactivity for both cyclin D1 and *c-myc*.²¹³

PLEOMORPHIC FIBROMA

Pleomorphic fibroma of the skin was described by Kamino *et al.* in 1989.²¹⁵ It presents as a slow-growing lesion, clinically indistinguishable from a polypoid skin tag.²¹⁶ A subungual lesion has been reported.^{217,218}

Histopathology

The lesion is usually a dome-shaped nodule with variable cellularity. The spindle-shaped cells show striking nuclear pleomorphism with rare mitotic figures (Fig. 34.8). A variant with myxoid stroma occurs.^{217,219} The cells express vimentin and CD34 but not desmin, Ki-M1p,²²⁰ or S100 protein, suggesting a possible origin from dendrocytes rather than myofibroblasts as originally thought.^{215,220} Staining for factor XIIIa has been moderate in some studies but negative or patchy in others.^{217,220,221} The nuclear atypia is similar to the ‘degenerative’ changes seen in a number of benign mesenchymal tumors.²²²

Differential diagnosis

The morphologic features of pleomorphic fibroma can resemble those of dermal atypical lipomatous tumor/well-differentiated liposarcoma. A clue to the diagnosis of pleomorphic fibroma is that any adipocyte foci that may be encountered lack cytologic atypia and may simply represent entrapped adipose tissue within the lesion.²²³ The importance of this finding is emphasized in the case of a cutaneous polyp that had some microscopic features of pleomorphic fibroma but also showed an area of adipocyte differentiation with pleomorphic lipoblasts and S100 positivity among tumor cells, resulting in a diagnosis of pleomorphic liposarcoma.²²⁴ Immunohistochemical and molecular analysis may be helpful in difficult cases; one study searching for 12q15/*MDM2* amplification by FISH analysis, and *MDM2* expression using immunohistochemistry, found negative results in all 15 cases of pleomorphic fibroma.²²³

SCLEROTIC FIBROMA (STORIFORM COLLAGENOMA)

Sclerotic (‘plywood’) fibroma is an uncommon fibrocytic neoplasm that occurs sporadically as a solitary lesion and also in a multifocal form in patients with Cowden’s disease.^{225–229} A solitary lesion may be the presenting feature of this syndrome.^{230,231} The terms ‘hypocellular fibroma’ and ‘circumscribed, storiform collagenoma’²³² have also been used for this entity. The lesions are flesh-colored papules or nodules measuring 0.5–3 cm in diameter. Sporadic cases, unassociated with Cowden’s disease, have been reported in the oral mucosa.^{233–235}

Figure 34.8 (A) Pleomorphic fibroma. (B) Some bizarre cells are present in the stroma. (H&E)

Although it was initially regarded as an involutional lesion, one study demonstrated ongoing type I collagen synthesis and deposition, suggesting that the lesion is a proliferating neoplasm.^{227,236} Local recurrence has been reported.²³⁷

Histopathology

The lesions are circumscribed, unencapsulated dermal nodules, often with an attenuated overlying epidermis.²²⁷ They are composed of thickened and homogenized eosinophilic collagen bundles arranged in a laminated manner with intervening prominent clefts.²³⁸ Vaguely storiform or whorled patterns of collagen may be present (Fig. 34.9). The lesions are of low cellularity. The nuclei are tapered to stellate. Elastic fibers are absent from the lesion, but there is often some stromal mucin. Similar collagenous changes have been seen as a focal phenomenon in the vicinity of inflammatory lesions, such as folliculitis,²³⁹ and in dermatofibromas, nevi, angiofibromas, erythema elevatum diutinum,²⁴⁰ fibroadenoma of axillary accessory breast tissue,²⁴¹ and neurofibromas where the sclerosis may be more extensive.^{242,243} This has led

Figure 34.9 (A) Sclerotic fibroma. (B) There is a storiform and whorled pattern. (H&E)

to the view that sclerotic fibroma-like change may represent a common reaction pattern in the skin.²⁴³

The spindle cells stain for vimentin and factor XIIIa.^{236,244} CD34 positivity occurs focally, with no consistent localization.^{236,245,246} The finding of diffuse CD34 and CD99 positivity in both sclerotic fibromas and pleomorphic fibromas has led to the suggestion that these tumors may be linked in some way.²⁴⁷ Both PCNA and Ki-67 immunoreactivity have been detected, as would be expected in a growing neoplasm.²²⁷ The proliferating index (MIB-1) was very low in another series.²⁴⁷

The lesion reported as a **pacinian collagenoma** is probably a variant.²⁴⁸ It was composed of paucicellular collagen fibers arranged in concentric lamellations giving an 'onion-skin' appearance. The cells stained for CD34. It had some resemblance to the perineurioma (see p. 1046).

Cases resembling sclerotic fibroma but with variable numbers of bizarre, multinucleated cells, often with a foamy cytoplasm, have been reported as **pleomorphic sclerotic fibroma**, **giant cell collagenoma**, and **cellular storiform collagenoma**.^{246,249–253}

Electron microscopy

The widened collagen bundles contain tightly packed collagen fibrils, only 50 nm in diameter.²³⁸ A recent ultrastructural study found that spindle cells with myoid features had proliferated around blood vessels.²⁵⁴

Differential diagnosis

In addition to the other lesions that can occasionally show changes of sclerotic fibroma, noted previously, differential diagnostic

considerations include two uncommon neural tumors: sclerotic perineurioma²⁵⁵ and a variant of pacinian neurofibroma, which has also been termed fibrolamellar nerve sheath tumor.²⁵⁶ The sclerotic perineurioma features dense connective tissue but also epithelioid and spindle cells in trabecular or whorled arrangements; these cells are positive for epithelial membrane antigen, as is typical for cells of the perineurium. The pacinian neurofibroma, or fibrolamellar nerve sheath tumor, is said to closely resemble sclerotic fibroma but may feature increased amounts of mucin (which, however, is also found in sclerotic fibromas), scattered cells with small nuclei, some of which can be S100⁺, and occasional pigmented dendritic melanocytes.²⁵⁷ A recent report described similarities between sclerotic fibroma and solitary fibrous tumor of the oral cavity. The distinction appeared to rest on the increased cellularity of the latter. The constituent cells of both were positive for vimentin, CD34, and CD99; bcl-2 positivity was evident only in the example of solitary fibrous tumor.²⁵⁸

COLLAGENOUS FIBROMA (DESMOPLASTIC FIBROBLASTOMA)

Collagenous fibroma, a recently described tumor, may arise in the subcutaneous tissue or muscle.^{259,260} Dermal involvement is rare.^{261,262} The tumors are firm and nontender. Most measure 2 or 3 cm in diameter, but larger lesions have been reported.²⁶³ There is a predilection for adult males.²⁶⁴ Any part of the body may be involved.²⁶⁴ Cases involving the oral cavity have been reported.^{265,266}

Few cases have been subject to cytogenetic analysis. It appears that a specific breakpoint of 11q12 occurs, combined in several cases with a reciprocal translocation.²⁶⁷ A recent report has shown a t(2;11) translocation in a case of collagenous fibroma,²⁶⁸ whereas another found trisomy 8 as the only cytogenetic abnormality.²⁶⁹

Surgery is the treatment of choice, with no reports of recurrence.²⁶⁷

Histopathology

Collagenous fibroma is usually a well-demarcated tumor in the subcutis, although some infiltration is often present at the periphery. It is hypocellular and composed of large, stellate, or spindle cells set in a densely collagenous or fibromyxoid stroma. There are usually no mitoses. There are inconspicuous small vessels. The cells express vimentin. They are focally positive for α -smooth muscle actin and muscle-specific actin.²⁶² Factor XIIIa was present in one case. S100 protein and CD34 are not expressed. Scattered cells may show a myofibroblastic immunophenotype.²⁷⁰

Differential diagnosis

One important differential diagnostic consideration is fibromatosis (see later discussion), a term applied to a group of tumors that tend to recur following local excision. In contrast to collagenous fibroma, the lesions of fibromatosis are typically more cellular, have fascicular arrangements of cells, and show greater degrees of peripheral infiltration. Nuclear β -catenin staining is also commonly present in forms of fibromatosis but has been reported to be negative in examples of collagenous fibroma.²⁶²

KNUCKLE PADS

Knuckle pads (discrete keratodermas over the knuckle and finger articulations) are well-formed skin-colored nodules overlying the interphalangeal and metacarpophalangeal joints of the hands.²⁷¹⁻²⁷³ They are usually multiple. There are several clinical variants, including a familial

group, an occupational or recreational-related group, and an acquired idiopathic group. They have followed the prolonged playing of video games.²⁷⁴ An association with knuckle cracking and with pseudoxanthoma elasticum has been reported.^{275,276} Of historical interest is the prominent knuckle pad on the right thumb of Michelangelo's statue of David.²⁷⁷

Inherited knuckle pads of the feet have been described in association with leukonychia and deafness, with and without keratosis palmoplantaris, including epidermolytic palmoplantar keratoderma.^{278,279} Genetic abnormalities found in the knuckle pad–palmoplantar keratoderma association include a mutation in the 2B rod domain of keratin 9²⁷⁸ and a G59A mutation in the *GJB2* gene, encoding the gap junction protein connexin.²⁸⁰ They have also been associated with acrokeratoelastoidosis.²⁸¹ They are well-defined plaques on the dorsal aspect of the feet. Acquired lesions of the feet have been associated with repetitive friction from athletic gear.²⁸¹ An example of granuloma annulare mimicking knuckle pads has been described.²⁸²

Histopathology²⁷⁷

There appear to be at least three histological types. The usual lesions show prominent hyperkeratosis, hypergranulosis, and epidermal acanthosis. There is minimal thickening of the papillary dermis. Another type has macronodules of swollen collagen fibers surrounded by thickened elastic fibers.²⁸³ A third variant with prominent subcutaneous fibrosis, belonging to the fibromatoses, has been documented.²⁷⁷

PACHYDERMODACTYLY

Pachydermodactyly is characterized by fibrous thickening of the lateral aspects of the proximal interphalangeal joints of the fingers, usually in males.²⁸⁴⁻²⁸⁹ The thumbs and fifth fingers are usually not involved. More extensive lesions have been reported.^{287,290,291} It has been reported in two siblings.²⁹²

Pachydermodactyly is regarded as a localized form of superficial fibromatosis. Trauma, such as finger rubbing, has been implicated in the etiology.^{293,294} In fact, repetitive trauma (e.g., from sporting or occupational activities or related to tic-like behaviors, obsessive-compulsive disorders, or Asperger syndrome) has been considered a precipitating factor in at least one-third of cases.²⁹⁵⁻²⁹⁷ It has also been suggested that this entity might be related to knuckle pads (discussed previously).²⁹⁸

Histopathology

The overlying epidermis shows hyperkeratosis and acanthosis. There is thickening of the dermis, with coarse collagen bundles in haphazard arrangement and a mild proliferation of fibroblasts. Increased fibroblastic activity and collagen deposition around sweat glands have been noted.^{292,299} Deposits of mucin of varying degrees are sometimes present in the interstitium,²⁸⁷ and elastic fibers are reduced. There is no inflammation. Types III and V collagens are mainly found.²⁹⁵

Differential diagnosis

Self-healing juvenile cutaneous mucinosis can present with fibromucinous nodules in a periarticular distribution on the hands that could be confused with pachydermodactyly. However, fusiform swelling of the lateral digits is not observed in the former condition, and patients frequently have lesions in other locations, including the head, face, and trunk.²⁹⁵ Microscopically, the lesions of self-healing juvenile cutaneous mucinosis are quite different in that they feature considerable dermal mucin deposition with mild perivascular inflammation. In subcutaneous lesions, there may be large mucinous lobules, sometimes accompanied by stellate, rhabdoid, or ganglion-like giant cells, creating a resemblance to proliferative fasciitis.

NODULAR FASCIITIS

Nodular fasciitis is a reactive proliferation of myofibroblasts with a predilection for the subcutaneous tissues of the forearm, upper arm, and thigh of young and middle-aged adults.^{300,301} Dermal and intravascular variants have been reported.^{302–307} Intradermal variants tend to occur in young adults and arise in the extremities or trunk, and they show a similar clinical course and biologic behavior to traditional nodular fasciitis.^{308,309} It usually grows quite quickly to reach a median diameter of 1.5 cm. Multiple lesions have been reported.³¹⁰ Recurrences are rare, even after incomplete surgical removal, and their occurrence should lead to a reappraisal of the original histological diagnosis.^{311,312} The diagnosis can usually be made readily by fine needle aspiration.³¹³ Regression of the lesion has followed this procedure.³⁰⁷ Regression may also occur after the use of intralesional corticosteroids.³¹⁴ Despite having high activity for proliferating cell nuclear antigen (PCNA), the cells do not express p53 or show aneuploidy.^{315,316} It is polyclonal and a reactive process.³¹⁷ Recent work found that a high percentage of cases of nodular fasciitis demonstrate fusion of the myosin heavy chain 9, nonmuscle (MYH9) promoter region to the coding region of ubiquitin carboxyl-terminal hydrolase 6 (USP6), with the latter being involved in another translocation associated with aneurysmal bone cysts.^{318,319} The authors of this study propose that this may serve as a model of transient neoplasia.³¹⁸

Cranial fasciitis of childhood is a distinct clinical variant arising in the deep soft tissues of the scalp, with involvement of the underlying cranium.^{320–322} Conservative surgical excision is curative.^{323,324} Intralesional corticosteroids were used in one case with a successful outcome.³²⁵

Histopathology^{300,326,327}

Nodular fasciitis is composed of a proliferation of spindle-shaped to plump fibroblasts that may be arranged in haphazard array ('tissue culture appearance') or in bundles that form S-shaped curves (Fig. 34.10).³²⁷ A vague storiform pattern is sometimes present focally. Mitoses are frequent, but atypical forms are rare. Cleft-like spaces may be seen between the fibroblasts. There is a variable amount of myxoid stroma and extravasated erythrocytes. Collagen is usually sparse. Capillaries with plump endothelial cells are common. Scattered lymphocytes are dispersed throughout the lesion.

Intravascular fasciitis, in which the proliferation occurs within small and medium-sized arteries and veins, appears to represent an origin from myofibroblasts within vessel walls rather than extension from the extravascular component that is often present.^{304,328} It is not associated with aggressive growth or metastasis.³⁰² Vascular involvement results in a plexiform appearance.

Less common findings include the presence of bone and cartilage;^{327,329,330} osteoid is not uncommon in the variant known as cranial fasciitis.³²⁰ Scattered multinucleate fibroblasts and osteoclast-like giant cells are often present, and, occasionally, the latter cells are quite numerous.^{311,327} The term '**ossifying fasciitis**' has been used if there is a significant component of osteoid or bone.³³¹ A variant with numerous cells resembling ganglion cells, akin to those seen in proliferative myositis,^{332,333} may be separated as a distinct entity – **proliferative fasciitis** (Fig. 34.11).^{334–336} Several examples of intradermal proliferative fasciitis have now been reported.^{337–339}

Various histological subtypes of nodular fasciitis have been proposed based on the cellularity, the amount of myxoid stroma, and the presence of collagen or other histological features, such as osteoclast-like cells, ganglion-like cells, or bone. Some of the proposed subtypes merely reflect changes in the histological composition during the evolution of the lesion.³⁰⁰

Immunoperoxidase studies demonstrate HSP47 (a useful marker of skin fibroblasts),³⁴⁰ smooth muscle actin, muscle-specific actin,

Figure 34.10 Nodular fasciitis. (A) A condensed fibrous capsule surrounds a tumor that is composed of swirling bundles of spindle-shaped cells set in a myxoid stroma. (B) Elongated spindle cells have a 'tissue culture-like' appearance. Along the upper portion of the figure, there are inflammation and erythrocyte extravasation. (H&E)

calponin, vimentin, and KP1, but not desmin, CD34, cytokeratin, or S100 protein.^{303,307,341–343} A similar staining pattern is seen in proliferative fasciitis, although the ganglion cells express only vimentin.³³⁶ The multinucleate cells in cranial fasciitis stained for CD68 in one reported case.³²⁴ Ki-67 expression can be high in nodular fasciitis, but this does

Figure 34.11 Proliferative fasciitis. Ganglion-like cells are present within a spindle cell tumor. (H&E)

not imply a likelihood of recurrence.³⁴⁴ In one study of nodular fasciitis of the head and neck, there was consistent positivity for smooth muscle actin, calponin, CD10, and PG P9.5; CD34 and CD56 were negative in all cases.³⁴⁵ The recently reported cases of intradermal proliferative fasciitis have shown an absence of smooth muscle actin staining among ganglion-like cells but, in some cases, expression of factor XIIIa, suggesting fibroblastic rather than myofibroblastic lineage.^{337–339}

Electron microscopy

Few ultrastructural studies have been carried out, but in one study of eight cases, myofibroblasts were the predominant cell present.³⁴⁶ Cells with features of fibroblasts or histiocytes are also seen.³⁴² Myofibroblasts and fibroblasts are also present in cranial fasciitis.³²¹

Differential diagnosis

Nodular fasciitis must be distinguished from fibrosarcoma and malignant fibrous histiocytoma. In addition to its characteristic subcutaneous location and rapid growth, nodular fasciitis lacks the dense cellularity, herringbone pattern, and marked mitotic activity expected in fibrosarcoma or the marked pleomorphism seen in many examples of malignant fibrous histiocytoma (MFH). The interconnecting fascicles of bland-appearing fibroblasts, dense collagen, and pronounced skeletal muscle infiltration associated with forms of fibromatosis help distinguish this group of lesions from nodular fasciitis. Deep fibrous histiocytomas can often be distinguished by whorled or 'curlicue' arrangements of cells, dense collagen, and sometimes by the presence of hemosiderin, lipid-laden macrophages, and Touton-like giant cells. Based on the study of head and neck nodular fasciitis by Morgen *et al.*, CD10 positivity would argue against leiomyosarcoma (usually CD10⁺); calponin expression against myofibroblastic sarcoma; PGP 9.5 positivity (and CD34 negativity) against DFSP; and CD56 negativity against malignant peripheral nerve sheath tumor, schwannoma, leiomyoma, or leiomyosarcoma.³⁴⁵

ATYPICAL DECUBITAL FIBROPLASIA (ISCHEMIC FASCIITIS)

Atypical decubital fibroplasia (ischemic fasciitis) is a pseudosarcomatous proliferation, found in immobilized or debilitated patients, that is different from a decubitus ulcer.³⁴⁷ The affected area measures 1–9 cm in diameter. It involves the shoulders, ribs, sacrococcygeal

Figure 34.12 Postoperative spindle cell nodule. This nodule is composed of cytologically bland spindle cells, and it features vasodilation and scattered inflammatory cells. (H&E)

region, and the tissues overlying the greater trochanter. There is involvement of the deep dermis, subcutis, and deep fascia with a zonal arrangement of fibrinoid necrosis, reactive fibrosis, neovascularization, fat necrosis, and ectatic vessels.^{347,348} Atypical fibroblasts are usually present. Microscopic changes resembling ischemic fasciitis have been found in the region of an intra-arteriolar cholesterol embolus.³⁴⁹

A study of 44 cases by Liegl and Fletcher found that there was an inconsistent association with immobility or debilitation.³⁴⁸

POSTOPERATIVE SPINDLE CELL NODULE

Postoperative spindle cell nodule is a rare lesion that develops soon after a surgical procedure in genital skin or the genitourinary system.³⁵⁰ Lesions have also been reported at other sites.³⁵¹ It is composed of spindle-shaped cells in a pattern of interlacing fascicles (Fig. 34.12). There are occasional mitotic cells. Vascular proliferation, hemorrhage, and inflammation accompany the process. The cells express vimentin; desmin and muscle-specific actin have been present in some cases.³⁵⁰ They do not express keratin.³⁵¹ A recent study of the cytology of this lesion showed bland spindled cells with eosinophilic cytoplasm, oval nuclei with inconspicuous nucleoli, and mitotic activity but without atypical mitoses.³⁵²

SOLITARY FIBROUS TUMOR

Solitary fibrous tumor was first reported by Klemperer and Rabin in 1931.³⁵³ It has been well-known to surgical pathologists as a tumor of the pleura or peritoneum that must be distinguished from mesothelioma. In recent years, it has been reported in a variety of other organs, including the orbit, oral mucosa, soft tissue, and skin,^{354–358} and therefore may be encountered by dermatopathologists. Skin lesions typically present as nodules and may be mistaken for cysts. Most cases have been on the head and neck;³⁵⁹ vaginal involvement has also been reported.^{360,361} Most patients with solitary fibrous tumor, both in skin and elsewhere, have been middle-aged to older adults, but children have developed the tumor and the editor has observed one case in an infant. Large pleural lesions may produce pulmonary symptoms or hypertrophic osteoarthropathy,³⁶² and hypoglycemia may occur in a few cases as the result of secretion of insulin-like growth factors.³⁶³

These symptoms have not been reported with cutaneous lesions to date.

Classically, the solitary fibrous tumor is benign, responding well to excision or wedge resection in the case of pleural tumors. However, 10–20% of lesions in other organs have been malignant.^{364–367} Cutaneous tumors have thus far behaved in a benign manner;³⁵⁵ one occipital lesion did show invasion of the underlying calvarium, but it responded to local excision with no recurrence in 6 months of follow-up.³⁵⁶

The tumor cells are predominantly fibroblastic, although focal myofibroblastic differentiation is often seen.³⁵⁴ This tumor was originally included with the hemangiopericytomas.³⁶⁸ No consistent (cyto) genetic alterations have been documented to date.³⁶⁶

Treatment of cutaneous cases is surgical excision of the lesion.

Histopathology

Solitary fibrous tumors are well circumscribed^{369,370} and found in the dermis and subcutis. They are composed of short spindled and ovoid cells with scant cytoplasm that are best known for forming a “patternless pattern,”³⁵⁸ although the cells may also be arranged in short fascicles or storiform configuration (Fig. 34.13).³⁵⁶ Cellular areas are interspersed with less cellular zones of thick, hyalinized collagen, occasionally with myxoid foci.^{355,358,369,370} Vessels may be numerous, and they may take on ‘staghorn’ contours, thereby mimicking hemangiopericytoma.^{355,358} Mast cells are not frequent in these tumors.³⁵⁶ The constituent spindled cells usually have a bland appearance, and mitotic figures are rare.³⁷¹ Malignant variants (not yet reported in skin) feature increased cellularity, pleomorphism, and mitotic activity. A value greater than four mitoses per 10 hpf has been used as a criterion to define malignant solitary fibrous tumors.³⁷²

The **giant cell angiofibroma**, originally described in the orbit and subsequently in other locations, including the skin, appears to be a giant cell-rich variant of solitary fibrous tumor.^{373,374}

Immunohistochemical staining regularly shows CD34 expression by spindle cells, and this feature has come to represent part of the definition of solitary fibrous tumor.^{356,370} Vimentin is also usually positive. Staining for bcl-2 is frequently observed.³⁵⁸ Focal staining for CD99 also occurs.³⁵⁷ Interspersed dermal dendritic cells are positive for factor XIIIa, and factor XIIIa⁺ dendrocytes were present in an oral lesion.³⁷⁵ Staining for desmin is usually negative, and negative results are obtained when staining for keratin and epithelial membrane antigen.³⁵⁶ The mesothelial markers calretinin and HBME-1 have not been detected in five dermal cases.³⁵⁹

Electron microscopy

On ultrastructural examination, there are cells with both fibroblastic and myofibroblastic features.³⁶⁹

Differential diagnosis

Spindle cell lipoma is potentially a close mimic of solitary fibrous tumor, as noted by Sigel and Goldblum.³⁷⁶ However, features of spindle cell lipoma that differ from those of solitary fibrous tumor include overwhelming occurrence in middle-aged to elderly men on the posterior neck or shoulder, interspersed mature lipocytes, and numerous mast cells. Hemangiopericytoma shares with solitary fibrous tumor both a similar morphology and immunohistochemistry, suggesting that these could be variants of the same entity. However, the spindled cells as well as their arrangements in solitary fibrous tumor differ from those of classic hemangiopericytoma. In contrast to solitary fibrous tumor, hemangiopericytomas lack hyalinized collagen and do contain mast cells.³⁵⁶ Furthermore, hemangiopericytoma-like foci are seen in a wide variety of tumors, some of which may actually represent myofibromas. Dermatofibromas often feature epidermal hyperplasia and xanthomatization, and CD34 expression is typically either absent or focal. Dermatofibrosarcoma protuberans (DFSP) is poorly circumscribed, usually

Figure 34.13 Solitary fibrous tumor. (A) There is variable cellularity. (B) The tumor is composed of spindle cells. (H&E)

has a distinctive storiform pattern, and lacks either thick, hyalinized collagen or prominent vasculature. The cells of monophasic synovial sarcoma of the spindle cell variety express keratin and epithelial membrane antigen and are negative for CD34, in contrast to solitary fibrous tumor.

FIBROUS HAMARTOMA OF INFANCY

Fibrous hamartoma of infancy is an uncommon fibroproliferative lesion of the subcutaneous tissue that is present at birth or develops in the first 2 years of life.^{377–381} It most frequently occurs around the shoulder, axilla, and upper arms, but cases involving the scalp,³⁸² inguinal region, scrotum,³⁸³ vulva,^{384,385} perianal area,³⁸⁶ and lower extremities^{387,388} have been reported. There have been examples of giant (10.5 × 8.5 × 4.5 cm) and/or multifocal lesions.³⁸⁹ There is a male predominance of 3:1.³⁷⁸ The clinical course is benign, despite its infiltrative appearance and tendency to local recurrence.³⁷⁹ It has been reported in an infant with Williams' syndrome (see p. 400).³⁹⁰ A reciprocal translocation [t(2;3)(q31;q21)] was present in one case.³⁹¹

Another study showed complex translocations that involved chromosomes 1, 2, 4, and 17.³⁹²

The subcutaneous tissue of excised lesions has a glistening gray-white appearance interspersed with fatty tissue. The involved area measures 2–8 cm in maximum diameter.

This tumor should be treated by complete excision; an aggressive approach should be avoided because the overall prognosis is excellent.³⁹³ Recurrences, when they happen, take place within the first year following surgery. However, a recent report described a case that recurred 14 years after the primary surgery.³⁹⁴

Histopathology^{378,395}

Fibrous hamartoma of infancy has poorly defined margins. It is centered on the subcutis. There are three different tissue components:^{378,396} interlacing trabeculae of fibrocollagenous tissue, small nests of loosely arranged mesenchymal cells, and interspersed mature fat (Fig. 34.14). The fibrous trabeculae vary in thickness and arrangement and contain spindle-shaped cells; they express vimentin but not S100 protein.³⁷⁹ Desmin and smooth muscle actin are found in the fascicular–fibroblastic regions.³⁹⁷ The myxoid areas are more cellular, with immature oval or stellate cells, sometimes having a whorled pattern. Sparse lymphocytes may be present in the stroma.

The overlying skin frequently shows eccrine changes that include hyperplasia, duct dilatation, intraluminal papillary formations, and

Figure 34.14 (A) Fibrous hamartoma of infancy. (B) There are bundles of fibrous tissue, some mesenchymal cells, and interspersed mature fat. (H&E)

squamous syringometaplasia.³⁹⁸ Primitive mesenchymal cells may replace the normal eccrine gland stroma.³⁹⁹ Increased numbers of terminal hair follicles, microfollicles, abortive hair follicles, and epidermal basaloid follicular hyperplasia have also been reported.^{398–400} Another case that presented with clinical dimpling and small white nodules showed, on microscopic examination, partial dermal thinning, a follicular unit with features of folliculosebaceous cystic hamartoma, smooth muscle aggregates, and keratinous cysts.⁴⁰¹

Electron microscopy

The constituent cells have the features of myofibroblasts, although some fibroblasts are also present.^{382,402} Fibroblasts alone were present in one reported case.⁴⁰³ Primitive mesenchymal cells are present in the immature-appearing areas.³⁹⁷

DIGITAL FIBROMATOSIS OF CHILDHOOD

Digital fibromatosis of childhood (infantile digital fibromatosis,^{404,405} recurring digital fibrous tumor of childhood,⁴⁰⁶ inclusion body fibromatosis⁴⁰⁷) is a rare benign tumor of myofibroblasts with characteristic cytoplasmic inclusion bodies.³⁸⁰ It presents as a dome-shaped firm nodule, up to 1 cm in diameter, usually on the digits.^{408,409} The thumbs and great toes are spared.⁴¹⁰ Lesions are usually solitary, but a second tumor is sometimes noted at the time of presentation or develops subsequently.⁴⁰⁸ The tumors may be present at birth or appear in the first year of life.^{411,412} Onset in late childhood or adult life is rare.^{407,413,414} A history of preceding trauma has been reported.⁴¹⁵ There is a rare syndrome consisting of recurrent digital fibroma, focal dermal hypoplasia, and limb malformations.⁴¹⁶

A viral etiology was originally suspected because of the characteristic inclusion bodies, but all cultures have been negative, excluding this hypothesis.^{417–419} The inclusions are now known to be filamentous aggregations composed largely of actin.^{420,421}

The tumor often recurs after local excision; very occasionally, it may regress spontaneously, but this may be accompanied by functional impairment.^{422–424} Spontaneous regression increases after long-term follow-up, casting some doubt on the benefits of surgical excision with its high (up to 60%) recurrence rate.⁴²⁵ Intralesional fluorouracil has also proven effective in the treatment of this entity.⁴²⁴

Histopathology^{408,410,426}

The tumor is non-encapsulated and extends from beneath the epidermis, through the dermis, and usually into the subcutis. It is composed of interlacing bundles of spindle-shaped cells and collagen bundles. There may be some vertical orientation of the cells and fibers superficially (Fig. 34.15). The appendages become incorporated within the tumor. The nuclei of the cells are oval or spindle shaped, and some stellate forms may be present. There are only occasional mitoses. The cytoplasm of the cells merges imperceptibly with the collagen. There are characteristic small eosinophilic inclusion bodies within the cytoplasm of the tumor cells, often in a paranuclear position (Fig. 34.16A). A clear halo is sometimes discernible in well-stained sections. These bodies measure 2–10 μm in diameter, and they may be mistaken for red blood cells. They stain red with the Masson trichrome stain and deep purple with the PTAH method (Fig. 34.16B). They are periodic acid–Schiff (PAS) negative but actin positive.⁴²⁷ In addition, the inclusion bodies stain with antibodies to calponin 1 using an enzymatic antigen retrieval method.⁴²⁸

There are small capillaries and a few scattered elastic fibers in the stroma. Lymphocytes are variable in number.⁴²⁹ The overlying epidermis usually shows flattening of the rete ridges. Ulceration is rare.

The immunocytochemical localization of vimentin and muscle-specific actin in the proliferating cells confirms their myofibroblastic nature.⁴⁰⁷ The cells also express desmin.⁴²⁰

Figure 34.15 (A) Digital fibromatosis of childhood. (B) The spindle-shaped cells and some collagen bundles have a vertical orientation within the dermis. (H&E)

Figure 34.16 Digital fibromatosis. (A) Pale pink inclusion bodies, composed of actin, are present in the cytoplasm of the spindle-shaped cells. (H&E) (B) The inclusion bodies stain deep purple with the PTAH stain (arrows). (Phosphotungstic acid–hematoxylin)

Electron microscopy

The spindle cells are myofibroblasts,^{415,430} and the inclusion bodies are compact masses of amorphous and granular material with some discernible microfilaments but with no limiting membrane. Actin has been demonstrated within the myofibroblasts, and it has been suggested that the inclusions are masses of actin⁴⁰⁴ or, more likely, degradation products of it.⁴³¹ This viewpoint has subsequently been challenged.⁴³² Cultured tumor cells also develop inclusion bodies.⁴⁰⁴

ANGIOFIBROBLASTOMA

Fewer than 10 cases of angiofibroblastoma have been described.^{433,434} It presents as a solitary dermal nodule on the extremities.⁴³⁴ It consists of stellate and spindle-shaped cells, with the phenotype of fibroblasts, embedded in a fibromyxoid to dense fibrous stroma. Numerous capillary-sized vessels, often in small groups, are scattered throughout the stroma. Staining for HHF35 is focal and pale. A small population of dendritic cells within the tumor express factor XIIIa. All other spindle cell markers are negative.⁴³⁴ It needs to be distinguished from other fibromyxoid tumors of the skin.

Surgical excision has been curative.⁴³⁴

ANGIOMYOFIBROBLASTOMA OF THE VULVA

Angiomyofibroblastoma is a rare tumor of the vulva that may be confused with aggressive angiomyxoma of the pelvic soft tissues and vulval region, which appears to be a related tumor.⁴³⁵⁻⁴⁴² A pedunculated form of vulvar angiomyofibroblastoma has been described.^{443,444} Angiomyxoma is not considered further, although rare superficial tumors have been described.⁴⁴⁵

The morphologically similar lesion described in the male genital tract by Laskin *et al.* as having features of both angiomyofibroblastoma and spindle cell lipoma has been reclassified as **cellular angiofibroma** (discussed later). Angiomyofibroblastoma is often misdiagnosed clinically as a Bartholin's cyst.⁴⁴⁶ The tumors are well circumscribed, measuring 0.5–12 cm in diameter. They do not recur if completely excised. Sarcomatous transformation has been reported.⁴⁴⁷

Histopathology^{446,448}

The lesion is composed of an edematous stroma in which abundant blood vessels (predominantly of the capillary type) are irregularly distributed. Spindle cells, some of which are plump, are present in the stroma, often aggregated around the vessels. Some cells may have abundant hyaline cytoplasm. Hypercellular areas may be present. Wavy collagen bundles are scattered through the stroma. Intralesional fat is often present (Fig. 34.17). A lipomatous variant with abundant fat has been reported.⁴⁴⁹

The stromal cells express vimentin and desmin but not S100 protein, smooth muscle actin, or muscle-specific actin.⁴⁴⁶ Aggressive angiomyxomas may also be positive for desmin, although the staining is more variable.⁴⁵⁰

CELLULAR ANGIOFIBROMA

Cellular angiofibroma is a recently described benign mesenchymal tumor, usually of the genital region, with some histological resemblance to angiomyofibroblastoma and spindle cell lipoma.⁴⁵¹ It has an equal sex incidence. It occurs predominantly in middle-aged and slightly older individuals. The majority occur in the vulvovaginal region^{452,453} and the inguinoscrotal region.⁴⁵⁴ A case from the elbow has been reported.⁴⁵⁵ Most cases present as a painless mass that measures 0.5–25 cm in diameter. Lesions tend to be larger in males than in

Figure 34.17 Angiomyofibroblastoma. (A) This image shows an edematous stroma; abundant, irregularly distributed vessels; and plump spindle cells that tend to aggregate around the vessels. (B) Another portion of the lesion shows a hypercellular area. Fine, wavy collagen bundles are scattered through the stroma. (H&E) (Photomicrographs courtesy Mark R. Wick, M.D.)

females.⁴⁵¹ Recurrences are rare even in cases excised with positive margins.

Cases with deletions of the chromosome 13q14 region have been reported.⁴⁵⁶ A similar finding is seen in some spindle cell lipomas and in (extra)mammary myofibroblastoma.⁴⁵⁶ These deletions can span the *FOX1A1* and *RB1* loci.⁴⁵⁷ A monoallelic deletion of the *RB1* gene, encoding the tumor suppressor retinoblastoma protein, is found in cellular angiofibroma.⁴⁵⁸

Histopathology

Most cases are well-margined tumors located primarily in the subcutaneous tissue.⁴⁵¹ Cellular angiofibroma is composed of bland, spindle-shaped cells, short bundles of wispy collagen, and numerous

thick-walled and often hyalinized vessels. Intralesional fat is present in approximately 20% of cases.⁴⁵¹ Significant cytological atypia and mitoses are uncommon.

By immunohistochemistry, the tumor cells express vimentin and, in 60% of cases, CD34.⁴⁵¹ Approximately 20% express SMA, but none contains S100 protein or h-caldesmon.⁴⁵⁹ Cases occurring in both the vulva and the male genitalia have expressed estrogen and progesterone receptors.^{456,459,460} An analysis by Flucke *et al.* indicates that cellular angiofibroma, spindle cell lipoma, and mammary-type myofibroblastoma are parts of a spectrum of a single entity, with variations in morphology related to anatomic location.⁴⁵⁸ In fact, all of these can show monoallelic or biallelic loss of RB1.⁴⁵⁷

Chen and Fletcher described 13 examples of cellular angiofibroma with atypia or sarcomatous transformation.⁴⁶¹ Among the nine cases with sarcomatous transformation were two with features of pleomorphic liposarcoma, three with discrete nodules having features of atypical lipomatous tumor, and four with a pleomorphic spindle cell component. Sarcomatous areas showed multifocal or diffuse p16 expression; the three with features of atypical lipomatous tumor failed to stain for MDM-2 or CDK4. These changes did not appear to predispose to recurrence during a limited follow-up period.⁴⁶¹

Differential diagnosis

Despite the morphologic and immunophenotypic similarities between solitary fibrous tumor and the cellular angiofibroma, spindle cell lipoma, and mammary-type myofibroblastoma group, solitary fibrous tumors differ in that they have not shown monoallelic or biallelic loss of RB1.⁴⁵⁷

DERMATOMYOFIBROMA

Dermatomyofibroma is a benign tumor of fibroblasts and myofibroblasts first reported by Hügel in 1991.⁴⁶² It has a predilection for the shoulder girdle, axilla, and abdomen of young adults.^{463,464} There is a female predominance. Cases in young males have a predilection for the posterior neck.^{465,466} The lesions present as firm red-brown plaques or nodules, 1 or 2 cm in diameter; they may resemble a keloid.⁴⁶⁷ A hemorrhagic form has been reported.⁴⁶⁸ Linear and giant annular variants occur.^{469,470} A similar lesion has been reported under the term 'myoid fibroma'.^{471,472}

Conservative surgical excision is usually carried out. There is no tendency to local recurrence.⁴⁷³

Histopathology⁴⁷³

The tumor is a non-encapsulated plaque-like lesion composed of fascicles of monomorphic spindle cells predominantly orientated parallel to the skin surface; some intersecting bundles are present (Fig. 34.18).⁴⁷⁴ The cells have faintly eosinophilic cytoplasm and elongated vesicular tapering nuclei. The lesion fills the reticular dermis and sometimes extends into the upper subcutis. It spares the papillary dermis and adnexal structures. The stroma contains collagen bundles with an increase in small blood vessels. In the hemorrhagic variant (discussed previously), there are numerous capillaries and slit-like spaces resembling the plaque stage of Kaposi's sarcoma, but there is no staining for CD34 or HHV-8.⁴⁶⁸ Red cell extravasation is also present. Elastic fibers are preserved, and some are thicker than usual. There is usually a sparse chronic inflammatory cell infiltrate around the vessels.

Most of the tumor cells express vimentin and nonspecific muscle actin.^{474,475} They are negative for smooth muscle-specific actin, desmin, S100, CD34, and factor XIIIa.^{474,475}

Electron microscopy

There is a mixture of fibroblasts, myofibroblasts, and mesenchymal cells.^{463,476}

Table 34.1 Types of myofibromatosis

Solitary, infantile
Congenital, multiple without visceral involvement
Congenital, generalized with cutaneous and visceral involvement
Solitary cutaneous myofibroma of adulthood

INFANTILE MYOFIBROMATOSIS

The entity of infantile myofibromatosis, which is regarded as a proliferative disorder of myofibroblasts, was established by Chung and Enzinger in 1981 with their report of 61 cases.⁴⁷⁷ Previous reports had appeared under several designations, including congenital fibrosarcoma,⁴⁷⁸ congenital generalized fibromatosis,^{395,479,480} and congenital mesenchymal hamartoma.⁴⁸¹ Fletcher and colleagues suggested that the spindle cell component shows true smooth muscle differentiation rather than being of a myofibroblastic nature.⁴⁸² Requena *et al.* suggested an origin from myopericytes.⁴⁸³ More recently, Fletcher and colleagues described a spectrum of tumors showing perivascular myoid differentiation, which included adult cases of myofibromatosis (myofibroma).⁴⁸⁴

The lesions are solitary in approximately 70% of cases.^{477,485} Almost half of these are situated in the deep soft tissues, and the remainder are located in the skin and/or subcutaneous tissue.^{380,486} The head, neck, and trunk are the usual sites of involvement.^{477,485} The finger is an uncommon site.⁴⁸⁷ There is a male predominance. Most lesions are present at birth⁴⁸⁸ or appear in the first 2 years of life; onset in adult life has been recorded.^{489,490} The term 'cutaneous myofibroma' seems to be an appropriate designation for the solitary lesions occurring in adults.⁴⁹¹⁻⁴⁹⁴ Multiple acral myofibromas have been reported in a patient with generalized morphea.⁴⁹⁵

In approximately 30% of cases, the lesions are multicentric (congenital generalized fibromatosis; OMIM 228550) and involve the skin, soft tissues, bones, and, uncommonly, the viscera.^{477,496,497} They are usually present at birth, and there is a female predominance. Spontaneous regression of soft tissue and osseous lesions sometimes occurs,^{477,498-501} but cases with visceral involvement are usually fatal.^{477,485,502} Cases with systemic involvement and a favorable outcome have been reported.⁵⁰³ The various clinical types of myofibromatosis are shown in Table 34.1. Recurrence after a long period of quiescence

has been documented.⁵⁰⁴ Central nervous system abnormalities were present in one case.⁵⁰⁵ Both autosomal recessive⁵⁰⁶ and dominant inheritance with reduced penetrance have been proposed.^{504,507,508}

Macroscopically, the tumors measure 0.5–7 cm or more in diameter. They are grayish-white in color and fibrous in consistency.

The **plaque-like myofibroblastic tumor of infancy** is an exceedingly rare tumor that presents in the first few months of life.⁵⁰⁹ Histologically, it resembles a dermatofibroma – the diagnosis given by the author to a similar case seen some years ago.

The prognosis is excellent, with recurrence unlikely after excision; aggressive variants are rare.⁵¹⁰ The complex regional pain syndrome has followed the surgical excision of a solitary adult myofibroma.⁵¹¹ There is increasing evidence that adult myofibromas show overlapping features with the myopericytoma, a tumor derived from pericytes/perivascular myoid cells. This aspect is considered further later (see p. 985).

Histopathology^{477,482}

The nodules are reasonably well circumscribed, although there may be an infiltrative border in the subcutis. There are plump to elongated spindle cells with features of myofibroblasts. They are grouped in short fascicles. Delicate bundles of collagen separate or enclose the cellular aggregates (Fig. 34.19). Mitoses are variable in number, but they are not atypical.

Vascular spaces resembling those of hemangiopericytoma are often found in the center of the tumor.^{477,512} This gives most lesions a biphasic appearance, with a central hemangiopericytoma-like area and a peripheral leiomyoma-like region. A monophasic variant with a prominence of tiny capillaries has been reported.⁵¹³ Sometimes there is an intravascular pattern of growth. Necrosis, hyalinization, calcification, and focal hemorrhage may be present centrally.⁴⁸²

Immunoperoxidase studies have shown that the tumor cells are positive for vimentin and α -smooth muscle actin but negative for S100 protein, myoglobin, and cytokeratin.^{482,489,512} Conflicting results have been reported for desmin,^{486,493} although it has been negative in recently reported cases.^{493,514}

Electron microscopy

The cells have the ultrastructural features of myofibroblasts.⁴⁸¹ Primitive vascular formations, with a pattern of irregular clefts between adjoining cells, were noted by Requena and colleagues.⁴⁸³ Regressing lesions show vacuolation of the cytoplasm of spindle cells with their eventual disruption.⁵⁰²

Differential diagnosis

In addition to hemangiopericytoma (the infantile form of which may be identical to, or part of a spectrum that includes, infantile myofibromatosis), the differential diagnosis of myofibroma includes leiomyoma,⁵¹⁵ forms of fibrous histiocytoma; neurothekeoma; and other tumors that may contain myofibroblasts, such as dermatomyofibroma and nodular fasciitis. Biphasic lesions of myofibroma are characteristic, but older lesions or those with a predominance of spindle cell fascicles can closely mimic not only leiomyoma but also other myofibroblastic lesions. Myofibromas lack the ‘tissue culture’ appearance of nodular fasciitis; the epidermal hyperplasia that accompanies traditional dermatofibromas; or the multilobulated, ‘compartmentalized’ configuration of the myxoid variant of neurothekeoma. More cellular variants of neurothekeoma, with positive staining for smooth muscle actin, can be more problematic because they can resemble leiomyoma and, by extension, some variants of myofibroma.⁵¹⁶ It remains to be determined whether the positive staining of cellular neurothekeomas for the melanocytic marker NKI/C3 might be a differentiating feature from myofibroma.

Figure 34.19 (A) Infantile myofibroma. (B) Short fascicles of plump, spindle-shaped cells are separated by thin bundles of collagen. (H&E)

PERIVASCULAR MYOMAS AND RELATED ENTITIES

‘Perivascular myoma’ is the suggested designation by Granter, Badizadegan, and Fletcher for a histological continuum of three lesional groups of tumor – myofibromatosis in adults, glomangiopericytoma, and myopericytoma – showing perivascular myoid differentiation.⁴⁸⁴ Hemangiopericytoma is another category of perivascular tumors, but

its existence has been questioned because several other lesions may have a similar growth pattern.⁴¹³ Perivascular myomas have been reported in patients of all ages, with a predilection for the subcutis and superficial soft tissues of the extremities.⁴⁸⁴ Some lesions are multifocal. This group of perivascular tumors has been further expanded in recent years by the addition of three further entities:

- Perivascular epithelioid cell tumor (PEComa)
- Clear cell myomelanocytic tumor
- Dermal clear cell mesenchymal neoplasm.

It seems that these tumors are derived from a perivascular cell with different immunohistochemical and morphological features to the perivascular myoma and the glomus tumor. They are considered next.

Myopericytoma

Myopericytoma was the term adopted by Fletcher and colleagues in 1998 for a tumor composed of a concentric perivascular arrangement of spindle cells with differentiation toward perivascular myoid cells.⁴⁸⁴ Requena *et al.* had used the term 2 years earlier in the text of their article on adult myofibromas to highlight the myopericytic differentiation that they perceived in this lesion.⁴⁸³ This spectrum of growth patterns, ranging from myofibroma at one end to myopericytoma at the other, has been confirmed by others.^{517,518}

Myopericytomas occur predominantly on the distal extremities of middle-aged adults.^{517,519,520} There is a male predominance. Tumors are located in the dermis, subcutis, or soft tissues.⁵²¹ Despite marginal or incomplete excision, recurrence is uncommon. A malignant variant has been described.⁵²² Intravascular myopericytoma has been detected within subcutaneous veins, with reported sites including the thigh⁵²³ and infraorbital region.⁵²⁴

Histopathology

Myopericytomas are characterized by thin-walled vessels and a concentric perivascular arrangement of ovoid, plump spindled to round myoid cells. The appearances range from hypocellular, fibroma-like tumors to cases resembling angioleiomyoma, myofibroma, and 'hemangiopericytoma' (Fig. 34.20).⁵¹⁹ A biphasic zonation pattern is usually present.⁵¹⁷ Malignant cases show increased mitotic activity.⁵²²

Immunohistochemically, all cases express α -smooth muscle actin (Fig. 34.21), and most also express h-caldesmon.⁵¹⁹ Desmin is focally positive in a few cases. CD34 has been negative;^{525,526} intravascular myopericytoma was focally CD34 positive in one case.⁵²³

Electron microscopy

Among the features of myopericytes are elongation with irregularly thickened and focally duplicated basement membranes, 'peg and socket' junctions with adjacent endothelial cells, numerous pinocytotic vesicles, abundant thin microfilament bundles with dense bodies and adhesion plaques, poorly developed rough endoplasmic reticulum and Golgi, and pseudointracellular bodies (resulting from invagination of basement and plasma membranes).⁵²⁷ These cells form a morphologic continuum with pericytes and vascular smooth muscle cells.⁵²⁷

PEComa

The PEComa is a family of related mesenchymal tumors that includes angiomyolipoma, lymphangiomyomatosis, clear cell 'sugar' tumor of the lung, and similar lesions arising at a variety of visceral and soft tissue sites.⁵²⁸ These tumors all share a distinctive cell type, the perivascular epithelioid cell, which has no known normal tissue counterpart.⁵²⁸ PEComas variably express melanocytic and muscle markers, whereas S100 protein and cytokeratins are usually absent.⁵²⁹

PEComas are rare tumors that occur predominantly in soft tissue, the gynecological organs, kidneys, and thorax.^{530–532} Cutaneous cases

Figure 34.20 (A) Myopericytoma. (B) Vessels are less conspicuous than usual. (H&E)

are exceedingly rare;^{533,534} they may be more common in the lower limb.⁵³⁵ Occasional cases are associated with the tuberous sclerosis complex.⁵³⁰ Chromosomal aberrations were detected in all cases in one series, and these mostly consisted of chromosomal losses.⁵³¹ The frequent deletion of 16p in which the *TSC2* gene is located indicates that PEComas and angiomyolipomas are both *TSC2*-linked neoplasms.⁵³¹

A subset of deep tumors behaves in a malignant manner and approximately 20% metastasize.^{528,530,536,537} The sclerosing variant reported by Hornick and Fletcher had a predilection for the retroperitoneum.⁵³⁸ Only one case occurred on the abdominal wall.

Histopathology

This tumor is composed of nests and sheets of usually epithelioid but occasionally spindled cells with clear to granular cytoplasm and a focal association with blood vessel walls.⁵²⁸ Multinucleate giant cells are often present.⁵³⁰ High cellularity, high nuclear grade, and necrosis are present in up to one-third of cases. Vascular invasion is uncommon.⁵³⁰

Figure 34.21 Myopericytoma. The tumor cells stain strongly for smooth muscle actin. (Immunoperoxidase stain)

Nearly all PEComas show immunoreactivity for both melanocytic (HMB-45 and/or melan-A) and smooth muscle (actin and/or desmin) markers;⁵²⁸ they also express MiTF.⁵³⁹ An HMB-45 case has been reported in a tumor from the foot.⁵⁴⁰ They are negative for CD34.⁵³⁰ Approximately one-third of cases express transcription factor E3 (TFE3).⁵⁴¹ Cutaneous PEComas, however, do not express TFE3 and are negative for SOX-10, arguing against neural crest origin.⁵⁴² A detailed study by Ahrens and Folpe has shown that PEComas do not truly express CD1a, as had been suggested in previous work.⁵⁴³

Differential diagnosis

The differential diagnosis of cutaneous PEComa includes melanomas with clear cell or balloon cell changes, clear cell sarcoma, metastatic renal cell carcinoma, and clear cell mesenchymal neoplasm. Findings aiding in those distinctions include junctional melanocytic proliferation, S100 positivity, and negative staining for desmin (melanoma); eosinophilic cytoplasm, nested spindled to epithelioid cells with prominent nucleoli, wreath-like multinucleated giant cells, and t(12;22) (q13;q12) translocation (clear cell sarcoma); diffuse cytokeratin positivity, epithelial membrane antigen (EMA) positivity, and positive RCC staining (renal cell carcinoma metastasis); and negativity for melanocytic markers (clear cell mesenchymal neoplasm).⁵⁴⁴

Clear cell myomelanocytic tumor

This tumor belongs to the spectrum of PEComas.^{529,545–547} Fewer than 20 cutaneous cases have been reported, 7 of which were described by Mentzel *et al.*⁵²⁹ In this series, 6 cases arose on the lower extremities and 1 case on the upper limb, all in adult females. In all cases, an ill-defined dermal lesion with extension into subcutaneous tissue was noted.⁵²⁹ Despite incomplete/marginal excision in 3 of the cases, none has recurred locally so far.⁵²⁹ In a report from Fletcher and colleagues, this tumor is now regarded by them as a cutaneous PEComa.⁵³⁴

Histopathology

The tumors are composed of numerous blood vessels with a lace-like pattern and slightly thickened walls, surrounded by epithelioid cells containing clear or focally granular pale eosinophilic cytoplasm.⁵²⁹ The nuclei are round and vesicular.

Immunohistochemically, tumor cells express HMB-45, microphthalmia transcription factor (MITF), and NKI/C3.⁵²⁹ Perivascular expression of α -smooth muscle actin is uncommon.⁵⁴⁷ S100 protein and pancytokeratin are not expressed.⁵²⁹ Melan-A was positive in most cases in one series,⁵³⁴ but it was negative in the other report.⁵²⁹ Scattered cells express desmin and h-caldesmon.^{534,546} Focal calponin staining is sometimes present.⁵²⁹

Distinctive dermal clear cell mesenchymal neoplasm

This term was applied by Lazar and Fletcher to five cases of a tumor arising on the lower limbs of adults.⁵⁴⁸ The tumors were composed of large clear cells with vesicular nuclei centered on the reticular dermis. They usually extended into the subcutis but spared the papillary dermis.

All cases expressed NKI/C3, and two of the five expressed CD68. They were negative for S100, HMB-45, melan-A, and muscle markers.⁵⁴⁸ A further case that expressed NKI/C3 has been reported.⁵⁴⁹

McAlhany and LeBoit reported a further five cases in abstract form, stating that these lesions were the same as those reported as clear cell myomelanocytic tumor (discussed previously).⁵⁵⁰ The cytoplasm contained glycogen.

The immunohistochemical findings in their cases were as follows: strong positivity for NKI/C3 and nuclear MITF in all cases, variable positivity for CD68 and S100, four of five with focal positivity for HMB-45, and no staining for melan-A, or muscle markers.⁵⁵⁰ In their recent report on primary cutaneous PEComas,⁵³⁴ Fletcher and colleagues acknowledged that this entity was morphologically similar to cutaneous PEComa, but the authors did not accept that they were synonymous on the basis of the negative melanocytic markers of the distinctive dermal clear cell neoplasm.⁵³⁴

INFLAMMATORY MYOFIBROBLASTIC TUMOR

Inflammatory myofibroblastic tumor, also known as inflammatory fibrosarcoma, occurs predominantly in the lungs and mesentery, although the soft tissues of the head and neck, or the extremities, may be involved.^{551–553} The mean age at presentation is 13 years.⁵⁵² Systemic symptoms are often present. It appears to represent a spectrum of myofibroblastic proliferations, some of which have been included in the past as inflammatory pseudotumor, a heterogeneous 'entity'.^{25,554–556} Kerl and colleagues believe that inflammatory pseudotumor includes tumors with detectable myofibroblasts that represent inflammatory myofibroblastic tumor and a group best called plasma cell granuloma, which represents a reaction pattern found in disorders such as spirochete-induced fibroid nodules and localized chronic fibrosing vasculitis.^{555,557,558} HHV-8-specific DNA has been detected in one cutaneous case.⁵⁵⁹

This tumor has a potential for recurrence and persistent local growth.⁵⁶⁰ Metastases have been recorded, but no reliable morphological parameters have been identified that predict prognosis.^{551,561} A report of 59 cases by Coffin, Hornick, and Fletcher noted that metastases were confined to ALK-negative cases.⁵⁵² Approximately 50% of cases recurred locally.⁵⁵² It has been suggested that inflammatory myofibroblastic tumor and inflammatory fibrosarcoma are synonymous or closely related entities.⁵⁶² They have been regarded as synonymous here. It has been suggested that this tumor is derived from fibroblastic reticulum cells (myoid cells) and not from myofibroblasts.⁵⁶³

The neoplastic nature of this lesion has been confirmed by the finding of recurrent clonal aberrations involving chromosome 2p23 similar to the ones found in anaplastic large cell lymphoma.⁴⁵⁰ The fusion genes found are *ALK-TPM4* and *TPM3-ALK*.¹⁶⁵ Approximately 50–70% of all tumors harbor *ALK* gene rearrangements.⁵⁵²

Figure 34.22 (A) Inflammatory myofibroblastic tumor. (B) There is an intimate admixture of inflammatory cells and spindle-shaped cells. (H&E)

Surgery remains the preferred treatment option for this tumor. Re-excision can be effective in managing recurrences.⁵⁵² Adjunctive therapy such as radiation and chemotherapy have been used, but there have been insufficient cases for meaningful analysis.⁵⁵² Steroids and NSAIDs have also been used. The use of imatinib has been reported to be effective. The development of kinase inhibitors of *ALK* is awaited.

Histopathology

The lesions are characterized by an admixture of myofibroblasts and fibroblasts, usually arranged in short interwoven fascicles (Fig. 34.22).⁵⁶⁴ In addition, there is a polymorphic inflammatory cell component consisting principally of lymphocytes and plasma cells.⁵⁶⁴ Xanthoma cells are sometimes prominent. Myxoid areas and focal stromal hyalinization are usually present.

Immunoperoxidase stains for vimentin, muscle-specific actin, smooth muscle actin, and cytokeratin are usually positive, indicative

of a myofibroblastic tumor with admixed inflammatory cells.^{560,565} *ALK*-1 staining is present in approximately 50% of tumors.^{450,566} The staining pattern is usually cytoplasmic. Less consistent positivity is seen with desmin and the epithelial markers AE1/AE3 and CAM5.2.⁴⁵⁰ Skeletal muscle markers are negative.

CUTANEOUS MYXOID FIBROBLASTOMA

There have been several reports of a benign fibroblastic tumor, with a myxoid matrix, that does not fit into one of the recognized entities.^{567,568} The well-circumscribed tumor is confined to the dermis and composed of stellate and spindle-shaped cells arranged loosely in a fascicular pattern resembling 'tissue cultures of fibroblasts'. There is abundant stromal mucin. The cells express vimentin only and have the ultrastructural characteristics of fibroblasts.⁵⁶⁷ Lesions have developed on the nose of a 27-year-old woman⁵⁶⁸ and the upper arm of a 57-year-old man.⁵⁶⁹

FIBROMYXOID SARCOMA (LOW GRADE)

Low-grade fibromyxoid sarcoma (LGFMS) is a rare tumor characterized by bland histological features and a paradoxically aggressive clinical course.⁵⁷⁰⁻⁵⁷⁴ The **hyalinizing spindle cell tumor with giant rosettes** (low-grade fibrosarcoma with palisaded granuloma-like bodies) is a variant of low-grade fibromyxoid sarcoma.⁵⁷⁴⁻⁵⁷⁶ They share the same cytogenetic abnormality (discussed later).⁵⁷⁷ LGFMS has a tendency to develop in the deep soft tissues of young adults, whereas the myxofibrosarcoma occurs in older patients.⁵⁷⁸ A variant of LGFMS occurring in the superficial soft tissues has been described. It appears to affect children at a higher rate than the usual deep variant; its prognosis is also better than that of the deep tumors.⁵⁷⁹ Local recurrence is common; distant metastasis, particularly to the lungs, occurs in up to 50% of cases.

The majority of LGFMSs bear either the t(7,16)(q32-34;p11) or t(11,16)(p11;p11) translocations, resulting in *FUS*-*CREB3L2* or *FUS*-*CREB3L1* fusions, respectively.⁵⁷⁶ The former translocation is the more common.⁵⁷⁶ Several recent cases have been found that demonstrated a novel *EWSR1*-*CREB3L1* gene fusion in this tumor.⁵⁸⁰

The immunophenotype and ultrastructure suggest a fibroblastic tumor possibly with focal myofibroblastic differentiation. A recent study suggested a relationship to sclerosing epithelioid fibrosarcoma.⁵⁷⁶

Histopathology^{570,571}

The tumor consists of bland spindle cells, showing a mainly whorled or focally linear arrangement, set in areas with an alternating fibrous or myxoid stroma (Fig. 34.23A).⁵⁷¹ Cellularity is low to moderate, and mitotic figures are uncommon.⁵⁷⁰ The tumor cells are small, spindle to stellate, with pale, poorly defined cytoplasm. Unusual microscopic features include cell clusters, strands, and palisades; retiform networks; moderate nuclear pleomorphism in recurrent and metastatic tumors; cysts; osseous metaplasia; and a 'tigroid' pattern with alternating fibrous and myxoid foci.⁵⁸¹

In a comparative study with myofibroblastic sarcoma, LGFMS was found to be composed of bland spindle cells arranged in a whorled pattern with alternating myxoid and fibrous stroma, and few curvilinear vessels, whereas myofibroblastic sarcoma had prominent elongated curvilinear vessels and pseudolipoblasts, accompanied by abundant myxoid matrix.⁵⁷⁸

The hyalinizing spindle cell tumor with giant rosettes, a variant of LGFMS (*low-grade fibrosarcoma with palisaded granuloma-like bodies*), is characterized by a collagenized fibroma-like component,

Figure 34.23 Low-grade fibromyxoid sarcoma. (A) Alternating fibrous and myxoid areas can be seen. They contain spindle cells in a whorled configuration. (H&E) (B) With FISH analysis, a 'breakapart' probe demonstrates single red *FUS* signals in several tumor cells, indicating the presence of the t(7;16) translocation. (FISH image courtesy Mark R. Wick, M.D.)

cellular patches of hyperchromatic spindle cells, and hyalinized bodies ringed by nuclei giving the appearance of a rosette or palisaded granuloma.^{574,582}

Most tumor cells express vimentin, but occasional cells stain positively for actin, desmin, and cytokeratin.⁵⁷¹ There are also sporadic reports of CD34 positivity.⁵⁸³ Most fusion-positive tumors are EMA positive and CD34/S100/smooth muscle actin negative.⁵⁷⁶ MUC4, a transmembrane glycoprotein involved in cell growth signaling pathways, is expressed aberrantly in a number of carcinomas. Cytoplasmic staining for MUC4 has been found in all studied LGFMSs but is negative in a wide variety of other soft tissue tumors, with the exception of 30% of monophasic synovial sarcomas.⁵⁸⁴

FISH analysis for the *FUS* (16p11) gene rearrangement shows positive results in almost 70% of tested cases (Fig. 34.23B), in contrast to other possibly confounding soft tissue sarcomas, including myxofibrosarcoma/myxoid malignant fibrous histiocytoma, which fail to show this rearrangement.⁵⁸⁵

Differential diagnosis

The combination of clinical, histopathologic, and immunohistochemical features usually allows distinction of LGFMS from other cutaneous or soft tissue tumors. In particular, adequate sampling should permit differentiation from myxomas or other myxoid sarcomas; this is a potential pitfall when techniques such as fine needle aspiration cytology are used.⁵⁸⁶ Lesions that are positive for CD34 could also be confused with myxoid DFSP, although the latter tumor lacks the distinctive perivascular cuffing of slender spindled cells. LGFMS can resemble perineurioma in small biopsy specimens, and like perineurioma, LGFMS can express both epithelial membrane antigen and claudin-1.⁵⁸⁷ Epithelioid variants of LGFMS can be confused with epithelial tumors, including papillary thyroid carcinoma.⁵⁸⁸ Another related issue is the occasional resemblance to sclerosing epithelioid sarcoma, as suggested in a study from the French Sarcoma Group. The authors found that 7 of 52 non-LGFMS tumors (4 of which were diagnosed as sclerosing epithelioid fibrosarcoma) contained *DFUS/CREB3L2* transcripts, suggesting a relationship between these two tumors.³⁸² LGFMS can also resemble fibromatosis, but it differs in that it is more cellular and less fascicular than fibromatosis, tends to have less collagen, and features alternating fibrous and myxoid zones.⁵⁷⁶ By immunohistochemistry, LGFMS has greater expression of Ki-67, p53, and cyclin D1 and lesser expression of the nm23 gene product than does fibromatosis.⁵⁸⁹ LGFMS should also be distinguished from the similar-sounding low-grade myxofibrosarcoma (MFS); the latter tumor only rarely metastasizes. In contrast to LGFMS, MFS is more uniformly myxoid, lacks a whorled arrangement of bland spindled cells or alternating myxoid and fibrous areas, has greater cytologic atypia, and features prominent curvilinear capillaries. In addition, MFS has a higher Ki-67 and cyclin E labeling index and lower p21 and p27 expression.⁵⁷⁸

MYXOFIBROSARCOMA

Formerly regarded as a myxoid variant of MFH, myxofibrosarcoma is now considered to be a distinct entity on the basis of its reproducible cytoarchitecture and consistent clinicopathological characteristics.^{590–593} Myxofibrosarcoma is one of the most common fibroblastic sarcomas of older individuals.^{594–597} It is often located in the subcutaneous tissue of the limbs. Dermal involvement has also been reported, but in such cases the bulk of the tumor is usually in the subcutis in the form of ill-defined nodules.^{598,599}

Myxofibrosarcoma is believed to be derived from fibroblasts. A large number of immature dendritic cells are present in the stroma.⁶⁰⁰ The tumor is characterized by complex chromosomal aberrations, none of which is specific for this entity.⁵⁹²

Treatment is wide surgical excision, with at least a 2-cm clearance. Radiotherapy has also been used for cases with infiltrative morphology, although there is no evidence that this is of any value.⁵⁹⁸ Superficial tumors less than 5 cm in diameter have an excellent prognosis, whereas disease-specific mortality rates are significantly related to tumor necrosis, large size (>5 cm in diameter), and decreased myxoid areas.⁶⁰¹

Histopathology

There is a spectrum of histological changes ranging from hypocellular, low-grade myxoid tumors to high-grade pleomorphic sarcomas.⁵⁹⁴ When dermal involvement is present, it is usually predominantly myxoid in appearance, leading to confusion with benign myxoid neoplasms in small biopsy specimens.^{594,602} Low-grade areas are composed of abundant vacuolated, myxoid matrix with scattered spindled fibroblast-like cells and stellate cells. Intracytoplasmic mucin is present in some of these cells, giving a signet-ring appearance.⁵⁹⁴ The stroma contains curvilinear blood vessels. Intermediate-grade areas are more

cellular with more nuclear hyperchromatism and pleomorphism. High-grade tumors resemble what was called pleomorphic MFH in the past. Cases mimicking pleomorphic hyalinizing angiectatic tumor have been described.^{603,604}

Nascimento, Bertoni, and Fletcher reported 17 cases of an **epithelioid variant of myxofibrosarcoma** that accounted for less than 3% of myxofibrosarcomas in Fletcher's consultation material.⁵⁹² It appears to be a more aggressive variant with approximately 70% local recurrence and 50% metastasis.⁵⁹² The cases were characterized by alternating hypercellular and hypocellular myxoid areas, with the latter having prominent curvilinear blood vessels. The cellular areas had many epithelioid cells with round nuclei, vesicular chromatin, prominent nucleoli, and moderate amounts of eosinophilic cytoplasm.⁵⁹² Immunostains were negative for all markers studied.

In the more usual variant, strong staining with vimentin has been recorded, whereas scattered cells show myoblastic or histiocytic differentiation.⁵⁹⁴ CD34 positivity has been recorded in some cells.⁵⁹⁸ There is no staining with desmin, S100, EMA, or a keratin cocktail. The extracellular matrix has a heterogeneous composition that includes glycosaminoglycans and albumin.⁶⁰⁵

MYXOINFLAMMATORY FIBROBLASTIC SARCOMA

The myxoinflammatory fibroblastic sarcoma is a rare, low-grade sarcoma of the hands and feet.^{591,606,607} It has been described at other sites.^{608,609} It is thought to be of fibroblastic origin, but a synovial origin has not been excluded. Its low-grade nature has been questioned because metastases have been recorded.⁶¹⁰

Chromosomal abnormalities (translocations and supernumerary ring chromosomes) have been reported.⁶¹¹ There is a high incidence of a t(1;10)(p22;q24) translocation in myxoinflammatory fibroblastic sarcoma, and FISH analysis for TGFBR3 and MGEA5 has been recommended as a diagnostic test. There is also an amplification of VGLL3 on 3p12.⁶¹² The same abnormalities have been found in the morphologically distinct hemosiderotic fibrolipomatous tumor.⁶¹²

Histopathology

There are some histological similarities with myxofibrosarcoma but with the addition of numerous inflammatory cells.⁵⁹¹ Three types of tumor cell occur in this lesion: spindle cells, large bizarre ganglion-like cells (virocyte or Reed–Sternberg-like cells), and a variable number of multivacuolated cells resembling lipoblasts and seen mainly within the myxoid areas.⁶¹⁰ In most cases, CD34, epidermal growth factor receptor (EGFR), and CD163 are diffusely positive.⁶¹³

FIBROSARCOMA

Enzinger and Weiss defined a fibrosarcoma as a malignant tumor of fibroblasts that shows no evidence of other cellular differentiation.⁶¹⁴ There has been a marked decline in the diagnosis of fibrosarcoma as a result of the delineation of the fibromatoses as a diagnostic entity and the recognition of low-grade fibromyxoid sarcoma and its variants hyalinizing spindle cell tumor with giant (collagen) rosettes and sclerosing epithelioid fibrosarcoma (see later). Furthermore, other spindle cell tumors, which in the past were sometimes misdiagnosed as fibrosarcoma, such as spindle cell melanoma and spindle cell squamous carcinoma, as well as malignant peripheral nerve sheath tumors, can now be more confidently diagnosed with the assistance of various monoclonal antibodies and immunoperoxidase techniques. Malignant fibrous histiocytoma, although extant, also included cases that had previously been diagnosed as fibrosarcoma.

Very little has been written on fibrosarcoma in recent years.⁶¹⁵ However, because it is primarily a tumor of the deep soft tissues that

only rarely develops in the skin and superficial subcutis, only brief mention is made of it. Cutaneous fibrosarcomas may follow thermal burns and radiation therapy or result from extension of a tumor arising in deeper tissues. The tumor affects predominantly middle-aged adults, although there is an uncommon clinical subset involving neonates and young children (congenital-infantile fibrosarcoma).⁶¹⁶⁻⁶¹⁹

Congenital-infantile fibrosarcoma is much less aggressive than adult-type fibrosarcoma despite a similar histological appearance. It accounts for 20–50% of malignant soft tissue tumors in infants and neonates. Up to one-half may be present at birth, with the remainder appearing in the first 2 years of life.⁶²⁰ Approximately 70% develop on the extremities, with the remaining 30% occurring on the head and neck. Axial lesions are uncommon. The lesions may be highly vascular and masquerade clinically as a hemangioma.⁶²¹ A novel chromosomal translocation t(12;15)(p13;q25) has been identified in the congenital-infantile group.⁶²² This translocation gives rise to an *ETV6-NTRK3* gene fusion.^{165,622} It can be detected in paraffin-embedded tissue.⁶²³

The term '*fibrosarcoma, low-grade fibroblastic type*' has been used as a diagnosis of exclusion, for tumors not encompassed by the entities of low-grade fibromyxoid sarcoma and its histological variants.⁶²⁴ It remains to be determined whether this represents a distinct fibrosarcoma type.⁶²⁴ The cases reported as fibroblastic/myofibroblastic sarcoma of the skin are difficult to categorize.¹⁵⁴ There was a quantitative predominance of fibroblasts over myofibroblasts. All five cases were free of recurrence, although the follow-up period for some cases was short.⁶²⁵

Histopathology^{614,626}

Typically, fibrosarcomas are composed of interlacing fascicles of spindle cells forming a so-called 'herringbone' pattern (Fig. 34.24). Mitoses are common. There is a variable meshwork of collagen and reticulin between the individual cells, with the amount depending on the differentiation of the tumor.

The *sclerosing epithelioid fibrosarcoma* is composed of small to medium-sized cells with a clear or pale cytoplasm and arranged in cords and strands.^{627,628} The cells are surrounded by a prominent collagenous stroma (Fig. 34.25). It appears to be related to low-grade fibromyxoid sarcoma.

The *inflammatory* fibrosarcoma appears to be synonymous with the inflammatory myofibroblastic tumor (discussed previously).

Figure 34.24 Fibrosarcoma. Atypical spindled cells form a 'herringbone' configuration. (H&E)

Figure 34.25 Sclerosing epithelioid fibrosarcoma. Aggregates of epithelioid cells, forming cords and strands, are present within a dense collagenous stroma. (H&E)

The *congenital infantile* variant is usually more cellular and composed of smaller cells with prominent mitotic activity. Foci of necrosis may be present. Unlike the adult variant, the interlacing fascicular (herringbone) pattern is not always seen.⁶²⁰

The tumor cells express vimentin but not, as a rule, desmin, S100 protein, or smooth muscle actin.⁶¹⁹

MYOFIBROSARCOMA

Malignant tumors composed of myofibroblasts are increasingly being recognized, although their existence remains controversial.²⁸ They have a spectrum of histological grades, and this has led to a proliferation of terminology. Furthermore, some tumors contain a mixture of cells that mark for fibroblasts and myofibroblasts. In a review of myofibroblastic malignancies in 2004, Fisher classified myofibroblastic sarcomas as follows:²⁸

- **Low grade**
Myofibrosarcoma (myofibroblastic sarcoma)
Inflammatory myofibroblastic tumor
Infantile fibrosarcoma
- **Intermediate grade**
Myofibrosarcoma
- **High grade.**

Pleomorphic myofibrosarcoma (histologically identical to MFH)

Most cases of myofibrosarcoma occur in the oral cavity, deep soft tissues, and bone, but approximately 10% or more involve the subcutaneous tissue. Low-grade lesions are usually indolent and often cured by complete excision, whereas some intermediate-grade myofibrosarcomas may recur and even metastasize. Pleomorphic myofibrosarcomas are usually regarded as being the same as pleomorphic MFHs (see p. 1005).²⁸

Low-grade myofibrosarcomas (myofibroblastic sarcomas, low grade) are distinctive spindle cell tumors showing myofibroblastic differentiation.⁶²⁹ Of the 18 cases reported by Mentzel *et al.* in 1998, only 2 involved the subcutis.⁶²⁹ Recurrences and metastases were recorded for some of the cases, but there was no follow-up for the subcutaneous cases.⁶²⁹ Fisher subsequently suggested that at least 1 of these cases is likely to have been of intermediate-grade malignancy. Other series have been reported that have included low-grade and

intermediate-grade tumors.⁶³⁰ Unlike inflammatory myofibroblastic tumor, low-grade myofibrosarcoma (myofibroblastic sarcoma) is not a member of the family of ALK⁺ tumors.⁶³¹

Histopathology

Myofibrosarcomas are composed of stellate or spindled cells that have tapered or ovoid nuclei with small nucleoli and scanty or moderate amounts of eosinophilic cytoplasm with variably distinct cell boundaries.²⁸ The cells are arranged in fascicles, sheets, or storiform whorls, with variable collagenous or myxoid stroma. There is focal nuclear atypia. Abnormal mitotic figures are rare, and necrosis occurs in a minority of cases.²⁸

The majority of low-grade myofibrosarcomas are positive for smooth muscle actin, and fewer than half express desmin, usually focally.²⁸ Calponin is usually diffusely positive, whereas h-caldesmon is focally expressed in an occasional case.²⁸

Electron microscopy

This tumor is composed of myofibroblasts with variable rough endoplasmic reticulum, peripheral microfilaments, and sometimes fibronectin fibrils and fibronexus.^{28,632}

FIBROHISTIOCYTIC TUMORS

The term ‘fibrous histiocytoma’ was introduced for a group of tumors that share certain morphological features, such as the presence of fibroblast-like spindle cells and presumptive histiocytes – cells that were assumed to arise from a tissue histiocyte that could function as, or transform into, a fibroblast. Although these tumors appear to be histogenetically heterogeneous, it is still convenient to retain the term ‘fibrohistiocytic’ in a morphologically descriptive sense for tumors that show features of fibroblastic and histiocytic differentiation. Some of these tumors appear to be derived from the dermal dendrocyte. Others are of uncertain lineage.⁶³³

DERMATOFIBROMA (FIBROUS HISTIOCYTOMA)

The large number of terms that have been used for dermatofibroma (histiocytoma,^{634,635} fibrous histiocytoma,^{636–638} sclerosing hemangioma,⁶³⁹ nodular subepidermal fibrosis^{640,641}) reflects the remarkable variation in its histological features and continuing controversy regarding its histogenesis.⁶⁴² However, the presence of transitional patterns and different morphological components in the same lesion is strong evidence in favor of its basically common nature and histogenesis.⁶³⁶ There has been a tendency to use the term ‘dermatofibroma’ for the usual fibrocollagenous and storiform variant and to use ‘fibrous histiocytoma’ for some of the unusual variants.

Dermatofibromas are common, accounting for almost 3% of specimens received by one dermatopathology laboratory.⁶⁴³ There is a predilection for the extremities, particularly the lower, of young adults.^{634,643} There is a female preponderance.⁶⁴³ Rare sites of involvement have included the fingers,^{640,644} palms and soles,⁶⁴⁵ the scalp,⁶⁴⁰ the face,⁶⁴⁶ a vaccination scar,⁶⁴⁷ and within a tattoo.⁶⁴⁸ A study of 20 cases of dermatofibroma arising on the face suggested that lesions in this location behave the same biologically as do those occurring elsewhere on the body.⁶⁴⁹

Dermatofibromas are round or ovoid, firm dermal nodules, usually less than 1 cm in diameter. A ‘giant’ variant has been recorded.^{650–653} It preferentially develops on the lower limbs.^{654,655} Satellitosis is a rare finding at the edge of a giant dermatofibroma.⁶⁵⁶ Polypoid, flat, atrophic, and depressed configurations also occur.^{657,658} Both the Meyerson phenomenon and a halo of asteatotic eczema have been reported around a dermatofibroma.⁶⁵⁹ Lesions with a preponderance of histiocytes are

often larger, and the aneurysmal (angiomatoid) variants may measure up to 10 cm in diameter.^{660,661} Dermatofibromas are usually dusky brown in color, but aneurysmal variants may be red, and tumors with abundant lipid can be cream/yellow, particularly on the cut surface of the excised lesion. They often show a characteristic central white, scar-like patch on dermatoscopic examination^{662,663} and a delicate pigment network at the periphery. Other findings have been recorded,^{664–666} including homogeneous blue pigmentation simulating a blue nevus.⁶⁶⁷ Dermatofibromas are most often solitary, but two to five lesions are present in approximately 10% of individuals.⁶³⁴ Multiple lesions have been reported,^{668–671} usually as a rare complication of immunosuppressive therapy^{645,672–674} or AIDS.^{675–680} Eruptive lesions have appeared after the commencement of highly active antiretroviral therapy (HAART)⁶⁸¹ and in other clinical circumstances.^{682–690} Familial eruptive dermatofibromas have also been reported.⁶⁸⁸ There are only a few reports of patients with large numbers of tumors;^{638,691–696} one such case was reported as ‘disseminated dermal dendrocytomas’. This case may have been a different entity – progressive nodular histiocytosis (see p. 1151). Clinical variants include the aneurysmal type, already referred to,⁶⁶⁰ and the rare annular hemosiderotic histiocytoma in which multiple brown papules in annular configurations were present on the buttocks.⁶⁹⁷ Some authors regard the hemosiderotic dermatofibroma as an early stage in the development of the aneurysmal variant.⁶⁹⁸ Some aneurysmal lesions may recur.⁶⁹⁹ Spreading satellitosis has been reported in one case.⁷⁰⁰

Although regarded as a benign tumor or reactive inflammatory process that may uncommonly recur locally (see later), several cases of metastasizing cellular dermatofibroma have been recorded.^{701–704} Clonality has since been found in some cases of dermatofibroma, but no consistent karyotypic aberration has been found.^{705,706} Mentzel and colleagues have drawn attention to the aggressive nature of dermatofibromas arising on the face.⁷⁰⁷ They often involve deeper structures and have an increased rate of local recurrence. They need to be excised with wider margins than the classic type.⁷⁰⁷

The **deep fibrous histiocytoma**, initially reported by Fletcher in 1990, occurs in the subcutaneous or deep tissues.⁷⁰⁸ A larger series of 69 cases from Fletcher’s consultation files was reported in 2008.⁷⁰⁹ The series included 41 males and 28 females, ranging in age from 6 to 84 years. More than half were located on the extremities, but approximately 10% occurred in the deep soft tissues of the peritoneum, mediastinum, or pelvis.⁷⁰⁹ The nonvisceral lesions were subcutaneous in location. They were well-circumscribed tumors that ranged in size from 0.5 to 25 cm (median, 3.0 cm). Of those cases with available follow-up, 8 (22%) had a local recurrence, but in all 8 cases, the tumor had been marginally or incompletely excised.⁷⁰⁹ Metastases occurred in 3 patients; all ultimately died of the disease. Apart from their large size, the metastasizing tumors were otherwise identical to the other tumors.⁷⁰⁹ A case associated with a melanoma has been reported.⁷¹⁰

The **atypical fibrous histiocytoma** (dermatofibroma with monster cells)⁷¹¹ is another uncommon variant with a low recurrence rate and the rare development of distant metastases.⁷¹²

Fibroblasts, non-lysosome-containing histiocytes,⁶⁴¹ and endothelial cells have all been regarded at some time as the cell of origin.⁶³⁴ Dermatofibromas have been regarded by some authors as a benign tumor and by others as a fibrosing inflammatory or reactive process.^{711,713,714} In support of the latter concept is the history of trauma, blunt or piercing, recorded in up to 20% of cases.⁶⁴⁰ An insect bite has preceded the development of a dermatofibroma.⁶³⁴ HHV-8 has not been detected.⁷¹⁵ On the basis of the immunoreactivity of 30–70% of the constituent cells with factor XIIIa, an origin from the ‘dermal dendrocyte’ has been proposed.^{716–718} The dendritic cells appear to be derived from blood monocytes or a stem cell common to both.⁷¹⁹ Recent studies have found HSP47⁺ fibroblasts in dermatofibromas.^{340,720} They were the major constituent cells in the fibrocollagenous type. The authors postulated two cell lineages – fibroblastic and bone marrow-derived

monocyte/macrophages (dermal dendrocytes).⁷²⁰ A 2008 study concluded that a dermatofibroma is composed predominantly of cells of macrophage phenotype with a variable amount of myofibroblastic elements.⁷²¹ It has been suggested that fibroblastic tumor cell-derived stem cell factor is responsible for the epidermal hyperpigmentation that overlies dermatofibromas.⁷²²

Surgical excision (including shave excision) is the usual method of treatment. Recurrence is uncommon, even in cases with positive margins. Two exceptions to this statement exist. The cellular variant, which often extends into the subcutis, and dermatofibromas of the face need to be excised with wider margins than the classic type to prevent recurrence.⁷⁰⁷

Histopathology^{634,636,637}

Dermatofibromas are poorly demarcated tumors centered on the dermis. There is sometimes extension into the superficial subcutis that may take the form of septal extension or a well-demarcated bulge.^{723,724} A ‘pure’ subcutaneous form is exceedingly rare.⁷²⁵ A grenz zone of variable thickness is present in approximately 70% of cases.⁶³⁴ Sometimes this contains dilated vessels.⁶³⁴ Dermatofibromas are composed of a variable admixture of fibroblast-like cells, histiocytes (some of which may be xanthomatous or multinucleate), and blood vessels. The terms ‘nodular subepidermal fibrosis’, ‘histiocytoma’, and ‘sclerosing hemangioma’ were used in the past for variants in which one of these three components predominated. Currently, it is usual practice to refer to fibrocollagenous, histiocytic, and angiomatous variants to reflect these differences in composition.^{636,726} Storiform, aneurysmal (angiomatoid), and fibrous histiocytoma variants are also recognized (see later). Numerous other variants have been described in recent years. Many are histological curiosities. They are listed in Table 34.2.

The *fibrocollagenous type* has a predominance of collagen and fibroblast-like cells in an irregular or whorled arrangement (Fig. 34.26).⁶³⁶ Sometimes there is striking cellularity of the lesion beneath the epidermis, with less cellular areas deeply.⁶³⁶ The *lichenoid* dermatofibroma has a dense cellular infiltrate impinging on the undersurface of the epidermis producing basal cell damage that often leads to clefting.⁷²⁷ Mitoses are rare. Uncommonly, there is a high mitotic rate, but this does not necessarily indicate the likelihood of recurrence.⁷²⁸ Histiocytes are usually imperceptible, but there is a variable vascular component. Hemosiderin is sometimes present in the cellular areas, but it is uncommon elsewhere. Bone⁷²⁹ and calcification⁶⁴⁰ are rare constituents of the stroma. Another variant of the fibrocollagenous type has nuclear *palisading* and prominent Verocay-like bodies in part of the lesion, usually the center.⁷²⁶ This palisading variant is positive for vimentin and factor XIIIa.⁷³⁰ A rare variant with sclerotic areas resembling a sclerotic fibroma has been reported.⁷³¹ The author has seen several such cases.

Cases with a prominent *storiform* pattern are sometimes termed ‘fibrous histiocytoma’ to distinguish them from the more usual

Table 34.2 Histological variants of dermatofibroma

Fibrocollagenous	‘Monster’ cell
Storiform	Osteoclastic
Cellular	Myofibroblastic
Histiocytoma	Myxoid
Lipidized	Keloidal
Angiomatous	Collapsed angiokeloidal
Aneurysmal	Palisading
Clear cell	Atrophic
Granular cell	Subcutaneous
Halo	Combined

Figure 34.26 Dermatofibroma. (A) The epidermis overlying the dermal tumor is acanthotic and papillomatous. There is a central 'dell'. (B) The cells have a storiform arrangement. (H&E)

fibrocollagenous type.^{636,732} Included within this group is the so-called '*cellular benign fibrous histiocytoma*'.^{704,733,734} These tumors often extend into the subcutis; they sometimes recur locally after incomplete surgical removal.⁷³⁵ Normal mitotic figures are common in the cellular variant, and 12% of cases show central necrosis. Up to 60% of cases show focal positivity for smooth muscle actin in a minority of the cells. The cellular variant differs from DFSP by its smaller size, fewer mitoses, and less extensive involvement of the subcutis.⁷³² It is negative for CD34, in contrast to DFSP.⁷³³

Another variant of fibrous histiocytoma occurs in the subcutis and deep soft tissues.^{708,709} This *deep fibrous histiocytoma* consists of bland ovoid to spindle-shaped cells arranged in a storiform pattern with admixed lymphocytes.⁷⁰⁹ Just less than half have been monomorphic, whereas the others have had multinucleate giant cells, osteoclastic giant cells, and/or foam cells.⁷⁰⁹ In a significant number of cases, a hemangiopericytoma-like growth pattern has been present.^{709,736} Stromal hyalinization has sometimes been present. Expression of CD34 was present in 4% of cases, whereas smooth muscle actin was positive in 38% of cases.⁷⁰⁹

The cerebriform collagenoma occurring in patients with Proteus syndrome may have a distinctive storiform pattern that may even resemble a DFSP.⁷³⁷

The histiocytic variant ('*histiocytoma*') has nests and sheets of histiocytes in a poorly cellular collagenous stroma (Fig. 34.27).^{634,636,640,642} There are often many foam cells and giant cells, which may be of foreign body or Touton type.⁶³⁴ Hemosiderin and lipid are commonly

Figure 34.27 (A) Dermatofibroma (histiocytic variant). (B) Sheets of 'histiocytes', some with vacuolated cytoplasm, are admixed with spindle-shaped cells. (H&E)

present.⁶⁴⁰ Foam cells and cholesterol clefts may be prominent in dermatofibromas if there is underlying hyperlipoproteinemia.⁷³⁸ These foam cells are different from the clear cells seen in the rare *clear cell* dermatofibroma (Fig. 34.28), in which the intrinsic spindle cells have pale cytoplasm.⁷³⁹⁻⁷⁴² The *balloon cell* dermatofibroma also has a clear cell 'phenotype' (Fig. 34.29).⁷⁴³ The *granular cell* dermatofibroma has epithelioid cells with a granular cytoplasm (Fig. 34.30).⁷⁴⁴⁻⁷⁴⁸ More traditional-appearing areas are usually present.

Figure 34.28 Dermatofibroma of clear cell type. (H&E)

Figure 34.29 Dermatofibroma of balloon cell type. (H&E)

Figure 34.30 Dermatofibroma of granular cell type. (H&E)

Figure 34.31 (A) Dermatofibroma (aneurysmal variant). (B) There are large vascular spaces and abundant hemosiderin in the surrounding stroma. (H&E)

The *lipidized* variant, which tends to be large and situated around the ankle region, is composed of numerous foam cells, smaller numbers of siderophages, and stromal hyalinization, which is typically 'wiry', keloid-like, or osteoid-like.⁷⁴⁹ These stromal changes set it apart from the more usual histiocytoma variant. There is no abnormality in serum lipids in this group.⁷⁵⁰

In the *angiomatous* (vascular) variant, there are numerous small branching vessels in a variable collagenous stroma. Focal hypercellularity resembling that seen in the fibrocollagenous type is often present. Hemosiderin is present in approximately half the cases.

The *aneurysmal* (angiomatoid) variant is distinct, with blood-filled spaces occupying up to one-half of the lesion.^{660,751-754} These vary from narrow clefts to large cavernous cysts (Fig. 34.31). The vascular channels are surrounded by histiocytes that contain hemosiderin and by foam cells and fibroblasts.⁶⁶⁰ Squamous-lined cysts were present in the stroma of two cases.^{699,755} Solid areas with the more usual appearance of a dermatofibroma are almost invariably present.⁷⁵⁶ This feature, together with the presence of foam cells, allows a distinction to be made from Kaposi's sarcoma.⁷⁵¹ The aneurysmal variant of malignant fibrous histiocytoma is much more pleomorphic and is usually centered on the deeper soft tissues.

Large, bizarre cells with abundant foamy cytoplasm and hyperchromatic nuclei have been reported in some dermatofibromas.^{711,733,757-759} These 'monster cells' are sometimes binucleate or multinucleate.^{653,711,760} Pleomorphism varies from focal and minimal to moderate or marked.⁷¹² Atypical mitoses are found in one-third of cases.⁷¹² Numerous cells

Figure 34.32 (A) Atypical fibrous histiocytoma. (B) Giant ('monster') cells can be seen. (H&E)

express Ki-M1p.^{220,761} The term 'atypical fibrous histiocytoma' has also been used for this variant; it is the preferred designation (**Fig. 34.32**).⁷¹² In the review of 59 cases of *atypical fibrous histiocytoma* of the skin reported by Kaddu, McMenamin, and Fletcher in 2002, the authors noted multinucleated giant cells, sometimes hemosiderin-rich, and atypical mitoses in nearly one-third of cases.⁷¹² A variant of dermatofibroma with osteoclast-like giant cells (*osteoclastic*) has also been reported.^{762,763} In the *combined* dermatofibroma, two or more variant patterns coexist in a single lesion.⁷⁶⁴ A combined lesion with islands of indeterminate cells and eosinophils set in a spindle cell tumor with the features of a dermatofibroma has been reported.⁷⁶⁵

Two other rare variants are the *myxoid* dermatofibroma with abundant stromal mucin mimicking a cutaneous myxoma^{687,766} and the *keloidal* dermatofibroma with areas of thick eosinophilic collagen.⁷⁶⁷ In a variant called 'collapsing angiokeloidal' dermatofibroma, refractile eosinophilic material surrounds collapsed, small-caliber vessels. The material resembles keloidal collagen but is negative with Congo red and PAS; it fails to stain with antibodies to smooth muscle actin, type I procollagen, and type IV collagen.⁷⁶⁸ There is marked thinning of the dermis in the *atrophic* variant.⁷⁶⁹ The proliferating cells in this variant

Figure 34.33 Dermatofibroma with overlying sebaceous glands. (H&E)

appear to phagocytose the elastic fibers within the lesion.⁷⁷⁰ Ulcerated and erosive variants have also been described.⁷²⁷

Other histological changes that can be seen in dermatofibromas include the presence of lymphoid nodules.^{634,771} They are an uncommon finding. The lymphoid tissue is usually in the subjacent fat or at the periphery of the lesion.⁷⁷¹ Germinal center formation is faint but definite in many instances.⁷⁷¹ Mast cells and a sparse infiltrate of chronic inflammatory cells are sometimes present. A diffuse stromal infiltrate of eosinophils was present in one case.⁷⁷² Another uncommon finding is the presence of smooth muscle bundles in the adjacent dermis.⁷⁷³ *Myofibroblastic* differentiation may occur within the tumor cells.⁷⁷⁴ Rarely, it is a prominent feature.^{775,776} The cells express smooth muscle actin and HHF35.⁷⁷⁵ Eosinophilic globules measuring up to 10 μ m in diameter have been identified rarely in dermatofibromas; they stain red with Masson's trichrome method, negative with PAS, and among a number of immunohistochemical markers are positive only for vimentin.⁷⁷⁷ Halo dermatitis (Meyerson's phenomenon) around a dermatofibroma has also been described.⁷⁷⁸

A morphologically related entity is the epithelioid cell histiocytoma (see later), which is composed of large angulated epithelioid cells that have some resemblance to the cells of a Spitz nevus.⁷⁷⁹ It is considered separately because of its distinctive appearance.

Various changes may be present in the overlying epidermis in dermatofibromas.⁷⁸⁰ Acanthosis, sometimes with basal hyperpigmentation, is present in approximately 70% of lesions.^{781,782} Other changes include a seborrheic keratosis-like pattern,⁷⁸² epidermal atrophy⁷⁸² or, rarely, intraepidermal carcinoma;⁷⁸³ or pseudoepitheliomatous hyperplasia and focal acantholytic dyskeratosis.⁷⁸⁴ In 5–8% of cases, there is a spectrum of distinctive epidermal changes ranging from basaloid hyperplasia, often with rudimentary pilar structures, to undoubted basal cell carcinoma.^{635,780,785–787} Clear cell acanthoma changes have been seen overlying dermatofibroma; the authors speculated that this may have been an example of 'stromal induction' rather than a collision lesion.⁷⁸⁸ Sebaceous structures and sebaceous hyperplasia are uncommonly present (**Fig. 34.33**).^{635,789,790} Upregulation of the EGF-EGFR and the HH-Patched signaling pathways may be involved in this sebaceous hyperplasia.⁷⁹¹ Unequivocal basal cell carcinoma is uncommon,^{729,792} and some of the cases reported as this are examples of exuberant basaloid hyperplasia;⁷⁹³ the distinction is not always easy. Recently, a significant increase in CK20-stained Merkel cells has been demonstrated in these basaloid proliferations compared to basal cell carcinoma.⁷⁹⁴ It has been suggested that the hair follicle-like structures represent regressive changes in pre-existing follicles and not the induction of new pilar units.⁶⁴³ EGF or some other factor produced by the underlying tumor cells may be responsible for these proliferative changes.^{795,796} Loss of heterozygosity in

the patch gene is often present in the basal cell carcinoma-like changes in the epidermis.⁷⁹⁷

A small percentage of cells, usually at the periphery, are S100 positive.⁷²⁶ α_1 -Antitrypsin and macrophage markers such as CD68 and HAM-56 have been reported in some of the tumor cells.^{798,799} Vimentin and α -smooth muscle actin are often present in the spindle-shaped cells.^{800,801} The finding of factor XIIIa in many dermatofibromas provides a marker for this tumor,⁷¹⁶ although it is also present in acral angiofibromas, scars, keloids, and some atypical fibroxanthomas, but not in DFSP.⁷¹⁷ The staining in dermatofibromas is often restricted to the periphery of the lesions, leading some authorities to question its specificity for dermatofibromas.⁸⁰⁰ It is usually absent in the aneurysmal variant.⁷⁵⁴ It was initially thought that the use of CD34 and factor XIIIa staining would differentiate dermatofibroma from DFSP. Unfortunately, some overlap occurs,^{802,803} including the occurrence of indeterminate fibrohistiocytic lesions with a dual population of CD34 and factor XIIIa⁺ cells (see later). In a 2001 study of the immunohistochemical properties of dermatofibroma and DFSP, CD34 was strongly expressed in 25% of dermatofibromas and 80% of DFSP, whereas factor XIIIa was strongly expressed in 95% of dermatofibromas and 15% of DFSP.⁸⁰⁴ This same study demonstrated the strong expression of tenascin (an extracellular matrix glycoprotein) at the dermal-epidermal junction in all cases of dermatofibroma but not in any DFSP.⁸⁰⁴ Staining within the lesion was of no help in differentiating these two lesions. Similar results were recorded in an earlier study.⁸⁰⁵ MMPs are expressed in dermatofibromas but are not upregulated in DFSP.⁸⁰⁶ Procollagen 1 and syndecan-1 are also found in dermatofibromas.^{807,808} The expression of metallothionein has been reported in dermatofibromas but not DFSP.⁷²⁴ A high proliferative index detected by MIB-1 staining excludes the possibility of a common dermatofibroma⁸⁰⁹ but not the cellular or deep variant.⁸¹⁰ CD10, a marker for atypical fibroxanthoma and positive in many other tumors, is also expressed in dermatofibromas.⁸¹¹

Mentzel *et al.* investigated seven cases of aggressive dermatofibromas with recurrences or metastases. All had mitotic figures, and most showed tumor necrosis and/or infiltration of the subcutis. Chromosomal aberrations were found by array comparative genomic hybridization, even in benign-appearing tumor components, and this may prove to be a useful technique for evaluating dermatofibromas with atypical microscopic features.⁸¹²

On dermoscopy, typical findings in dermatofibroma include a peripheral pigment network and central white patch; however, a number of them can show atypical or 'non-DF' patterns, including those resembling melanoma, basal cell carcinoma, vascular tumor, collision tumor, or psoriasis.⁸¹³ A green color has been noted on dermoscopic examination of hemosiderotic dermatofibromas.⁸¹⁴

Electron microscopy

Ultrastructural studies have given conflicting results, with the cells variously reported as resembling fibroblasts, histiocytes, and even myofibroblasts.^{815,816} Endothelial cells with Weibel-Palade bodies were the prominent cell noted in one study.⁶³⁹ Vessels are conspicuous in the angiomatoid variant.⁷⁵² There is a need for a reappraisal of the ultrastructural findings in light of the immunoperoxidase studies implicating the dermal dendrocyte as the cell of origin (discussed previously).

Differential diagnosis

The resemblance of dermatofibroma to DFSP (see subsequent discussion) can be striking, especially in cellular or deep penetrating variants or where 'cartwheel' arrangements of nuclei can be observed. In contrast to dermatofibromas, lesions of DFSP tend to be larger or multinodular and typically lack overlying epidermal hyperplasia. The patterns of subcutaneous infiltration of DFSP include lace-like

infiltration of fat lobules or horizontally arrayed collections of spindled cells that parallel the epidermal surface, whereas dermatofibromas tend to have either bulbous, 'pushing' margins or 'vertical' subcutaneous infiltration along the septa.⁷²³ Deep penetrating dermatofibromas show perilesional lymphoid follicles and hyalinized collagen – features not identified in DFSP.⁸¹⁷ Polarizable collagen can usually be demonstrated within the substance of the tumor in dermatofibroma but is absent in DFSP.⁸¹⁸ Immunohistochemistry is also helpful; the characteristic profile of DFSP is CD34⁺ and factor XIIIa⁻, whereas that of dermatofibroma is CD34⁻ and factor XIIIa⁺. However, weak positivity for CD34, or positive staining of cells at the periphery of a lesion, is sometimes found in dermatofibromas. CD163 is usually positive in dermatofibroma and negative in DFSP, and this may be useful when used in a panel with CD68, factor XIIIa, and CD34.⁸¹⁹ Similarly, stromelysin 3 reliably stains dermatofibromas but is only occasionally expressed in DFSP.⁸²⁰ In the past several years, numerous studies have added to the immunohistochemical armamentarium for distinguishing these two tumors. The *CTHRC1* gene encodes a protein (collagen triple helix repeat containing-1) that plays a role in the cellular response to vascular injury. *Cthrc1* is expressed in most examples of DFSP, whereas most dermatofibromas are negative.⁸²¹ Recently, it has been noted that D2-40 (podoplanin), which recognizes a sialoglycoprotein and is most closely associated with lymphatic endothelium, apparently produces uniform, strong staining of dermatofibromas and is negative or shows only focal and faint stromal staining in DFSP.⁸²² Another recent study showed that cathepsin K, a cysteine proteinase with collagenolytic and elastolytic properties expressed during scar formation, was expressed in all studied cases of dermatofibroma but in none of the cases of DFSP.⁸²³ The MIC2 gene product, CD99, is strongly positive in dermatofibroma and moderately to weakly positive in DFSP. Significantly, the superficial dermal cells in DFSP were regularly negative for CD99, whereas comparable cells were routinely positive in dermatofibroma; this suggests that CD99 staining may be helpful in the differential diagnosis when interpreting superficial biopsy specimens.⁸²⁴ Dermatofibromas with atypical cells can be confused with **atypical fibroxanthoma**, and it is likely that some past reports of atypical fibroxanthoma on the extremities in younger individuals were actually examples of lipidized dermatofibromas with atypia. Small size, the presence of typical overlying epidermal changes, characteristic cell arrangements, and the absence of atypical mitoses are all points in favor of dermatofibroma. Immunohistochemistry alone may be of limited value in making this distinction; for example, significant percentages of both tumors are positive for factor XIIIa.

Dermatofibromas with myofibroblastic differentiation could be confused with cutaneous **leiomyoma**, particularly piloleiomyoma. In addition to architectural features, dermatofibromas (unlike most leiomyomas) are typically negative for desmin. Dermatofibromas can resemble **melanocytic tumors** under several scenarios. Sparsely or nonpigmented blue nevi or desmoplastic (sclerotic) nevi (including desmoplastic Spitz nevi) can closely mimic dermatofibroma and can even feature overlying epidermal hyperplasia. They differ by showing occasional sparse melanin pigmentation, identifiable with the Fontana stain, and positive immunohistochemical staining for Melan-A and (variably) for S100 or HMB-45.^{824–826} **Sclerotic fibroma** is regarded by many as a unique entity, but there is an opinion that at least some of these lesions may represent sclerotic variants of dermatofibroma,⁸²⁷ and foci with changes identical to those in sclerotic fibroma can occasionally be found within a dermatofibroma. Dermatofibroma can have a clinical resemblance to basal cell carcinoma; therefore, a superficial shave biopsy of a lesion showing basal cell hyperplasia could easily be interpreted as a superficial basal cell carcinoma. Knowledge that the basal cell changes are associated with a dermatofibroma can be useful. Such lesions are likely to have limited potential for biologic aggressiveness. There is a variant of **cellular neurothekeoma** that features a fascicular growth pattern, thickened peripheral collagen bundles with

collagen entrapments, and sometimes overlying epidermal hyperplasia, closely resembling dermatofibroma. Features that distinguish this variant from dermatofibroma include plump epithelioid cells with generous amounts of cytoplasm and nuclei with prominent nucleoli, a lobulated to micronodular growth pattern, and MiTF positivity without factor XIIIa expression.^{242,828}

EPITHELIOID CELL HISTIOCYTOMA

Epithelioid cell histiocytoma is regarded as a variant of fibrous histiocytoma (dermatofibroma).⁷⁷⁹ It is considered separately from dermatofibroma because of its distinctive histological appearance, which resembles to some extent the intradermal variant of Spitz nevus.⁸²⁹ The lesion usually presents as an elevated nodule on the extremities of adults, although other sites have been recorded.⁸³⁰ In one patient, a lesion on the arm was followed 1 month later by another lesion on the nostril.⁸³¹ Although a dendrocyte origin is usually favored, an endothelial cell origin has also been proposed on the basis of the ultrastructural findings in one case.⁸³² On the basis of immunohistochemistry, an origin from microvascular fibroblasts and dendritic cells has been proposed (see later).⁸³³ The term 'solitary epithelioid histiocytoma' has recently been proposed as a group term for tumors previously called reticulohistiocytoma and multicentric reticulohistiocytosis (see p. 1154).⁸³⁴ This is bound to lead to confusion.

Histopathology

The polypoid lesions often have an epidermal collarette.⁸³⁰ There is relatively sharp circumscription.⁸³⁵ All lesions are characterized by sheets of angulated epithelioid cells with abundant eosinophilic cytoplasm. Scattered mitoses are usually present. There are many small blood vessels, and there is often a perivascular mosaic pattern of epithelioid and plump spindle cells. Sometimes this results in hemangiopericytoma-like features.⁸³⁶ Conspicuous cellular whorls of spindle cells were present between the epithelioid cells in one case.⁸³⁷ Xanthoma and/or giant cells are often present in small numbers.⁸³⁸ The stroma contains a light mononuclear inflammatory cell infiltrate.⁸³⁰ A cellular variant, with one or more dermal nodules composed of large epithelioid cells, has been reported.⁸³⁹ It usually extends into the deep dermis. A granular cell variant has also been described.⁸⁴⁰ Rare cases occur with combined features of dermatofibroma and epithelioid cell histiocytoma (Fig. 34.34).

Factor XIIIa is expressed by 50–70% of the cells, whereas S100 and HAM-56 may be expressed by up to 5% of cells. HMB-45 is negative.⁸³⁹ The granular cell variant expresses CD68.⁸⁴⁰ The vascularity is confirmed by a CD31 or CD34 preparation.⁸⁴¹ Early lesions, but not late ones, contain up to 40% of CD34⁺ cells, leading to the suggestion that the constituent cells appear to arise from the activation of resident microvascular CD34⁺ dermal fibroblasts and the accumulation of factor XIIIa⁺ dendritic stromal-assembly histiocytes.⁸³³ Vimentin positivity was recorded in one study.⁸⁴²

Differential diagnosis

Epithelioid cell histiocytoma closely resembles the intradermal variant of Spitz nevus. Careful evaluation of multiple sections for junctional involvement can help exclude a subtle compound Spitz nevus. As a further argument against a melanocytic tumor, the cells of epithelioid cell histiocytoma are negative for S100 and HMB-45 and are often strongly positive for factor XIIIa. The granular cell variant of epithelioid cell histiocytoma can closely resemble morphologically the primitive polypoid dermal non-neural granular cell tumor, and this problem may be further compounded by its S100 negativity and sometimes weak staining for CD68 and factor XIIIa.⁸⁴³ Pyogenic granuloma (lobular capillary hemangioma) can also

Figure 34.34 (A) Epithelioid cell histiocytoma. (B) This case has both epithelioid cells and overlap features with dermatofibroma. (H&E)

resemble epithelioid cell histiocytoma, based on their shared features of a thinned overlying epidermis, epidermal collarette, prominent vasculature, and uncommon mitoses. However, epithelioid cell histiocytoma has factor XIIIa⁺ dendrocytes, epithelioid cells between vessels that are not arranged in lobules, and a lack of protuberant endothelial cells.^{844,845}

PLEXIFORM FIBROHISTIOCYTIC TUMOR

Plexiform fibrohistiocytic tumor is a rare tumor that involves predominantly the upper limb of infants and children.^{846,847} It presents as a slow-growing, painless mass. More than 100 cases have now been reported.⁸⁴⁷ It has an immunophenotype suggestive of myofibroblastic differentiation.^{848,849} Grossly, the tumor involves the superficial soft tissue, often arising at the dermal-subcutaneous junction.⁸⁵⁰ Dermal variants have been described.⁸⁵¹ The lesion is poorly demarcated, lobulated or micronodular. It is white-gray in color and averages 1–3 cm in size.⁸⁵²

Local recurrence is common, usually because of incomplete removal. Metastasis has been recorded,⁸⁵³ but not in infants.⁸⁵² It is included here with the fibrohistiocytic lesions, rather than the myofibroblastic tumors, because of the dual cell population.

Wide local excision is the recommended treatment.⁸⁵²

Figure 34.35 Plexiform fibrohistiocytic tumor. (A) This subcutaneous tumor has fibroblastic fascicles and histiocytic nodules. (B) Osteoclast-like giant cells are present in the nodules. (H&E)

Histopathology⁸⁵⁰

The appearances vary, depending on the relative proportion of the two major components: (1) fascicles of fibroblastic cells and (2) aggregates or discrete nodules of histiocyte-like cells. The fascicles often ramify, giving a plexiform appearance.⁸⁵² The 'histiocytic' nodules are composed of eosinophilic epithelioid cells. Osteoclast-like giant cells with 3–10 nuclei are often present (Fig. 34.35).⁸⁵⁴ Hemosiderin is often present in the stroma.⁸⁵² Granular cell change is a rare finding.⁸⁵⁵ A myxoid variant has also been reported.⁸⁵⁶ The cases reported as **plexiform xanthomatous tumor** had some areas resembling this lesion with the addition of numerous xanthoma cells.⁸⁵⁷

The tumor cells express vimentin, smooth muscle actin, but not factor XIIIa. They are positive with HHF35.^{847,851} A minority of the cells in the histiocytic nodules stain for CD68 but not CD45 or Mac387.^{850,853} The osteoclast-like giant cells are positive with KP1.⁸⁵¹

To date, specific chromosomal hallmarks have not been identified for this tumor, and molecular diagnosis of plexiform fibrohistiocytic tumor is not reliable with current methods.⁸⁵⁸

Electron microscopy

Ultrastructurally, the tumor cells have features of myofibroblasts and histiocyte-like cells.⁸⁴⁷

Differential diagnosis

The differential diagnosis includes dermatofibroma, plexiform neurofibroma, fibromatosis, and giant cell tumors, both benign and malignant; however, in most instances, the clinical, microscopic, and immunohistochemical features are sufficiently distinctive to allow an accurate diagnosis. Jaffer and co-workers noted significant morphologic and immunophenotypic similarities between plexiform fibrohistiocytic tumor and cellular neurothekeoma.⁸⁵⁹ Wartchow and colleagues suggested that ultrastructural studies may allow accurate distinction between the two in problematic cases.⁸⁶⁰ Despite the fact that both tumors express NKIC3 and CD10 and are often PAX2⁺, a recent study showed that MiTF was strongly and diffusely positive in cellular neurothekeoma and consistently negative in plexiform fibrohistiocytic tumor.⁸⁶¹ Jacobson-Dunlop *et al.* investigated the role of punch biopsy in diagnosing plexiform fibrohistiocytic tumor. Generally, those lesions with cellular and mixed variants were more readily diagnosable by this method because of their distinctive features, but the fibrous variant was more difficult to diagnose, resembling reactive myofibroblastic processes, sclerotic dermatofibroma, DFSP, or fibromatosis. Despite help from immunohistochemical studies, complete excision may be necessary in order to better appreciate all of the microscopic characteristics.⁸⁶²

GIANT CELL FIBROBLASTOMA

Giant cell fibroblastoma is a rare soft tissue tumor occurring predominantly in childhood.⁸⁶³ The back, thigh, and chest are the favored sites. The vulva is a rare site of involvement.⁸⁶⁴ There is a male predominance. Macroscopically, the tumor appears gray-pink with a partly gelatinous consistency.⁸⁶⁵ Cases recurring as, or transforming to, DFSP have been reported.^{866–869} Foci resembling giant cell fibroblastoma have also been seen within a DFSP (hybrid lesions),^{870,871} as has the phenomenon of a DFSP recurring as a giant cell fibroblastoma.^{872,873} Furthermore, both tumors have demonstrated cytogenetic abnormalities involving chromosomes 17 and 22, resulting in fusion of the *COL1A1* and *PDGFB* genes.⁸⁷⁴ These findings have led to the suggestion that giant cell fibroblastoma is a juvenile variant of DFSP. Giant cell fibroblastoma has been misdiagnosed as dermatofibroma.⁸⁷⁵

Wide local excision is the recommended treatment.⁸⁷¹ Local recurrence is common following incomplete surgical removal.⁸⁷⁶

Histopathology^{863,865,877–880}

The dermis and subcutis are involved by an infiltrating spindle cell tumor in which the tumor cells are embedded in a loose connective tissue matrix showing areas of mucinous change. Scattered through the tumor are uninucleate and multinucleate giant cells (which are actually multilobated). A characteristic feature is the presence of branching sinusoidal spaces lined by cytoplasmic extensions of the spindle and giant cells (Fig. 34.36).^{877,881} These cells are negative for S100 protein, desmin, muscle-specific actin, and factor VIII, but they show scattered positivity for α_1 -antitrypsin.^{877,878,882} Both the spindle cells and the giant cells stain consistently for vimentin.⁸⁸⁰ Although earlier reports gave conflicting results on the expression of CD34 by this tumor,⁸⁸³ recent reports have found positivity in a significant number of cases.⁸⁸⁴ The giant cells are almost invariably positive.^{883,885}

Electron microscopy

Ultrastructural examination of this tumor has shown the cells to be fibroblasts, some of which have cytoplasmic extensions.⁸⁶⁵ Cross-striated fibrils have been demonstrated in the cytoplasm of the cells.⁸⁸⁶

Figure 34.36 Giant cell fibroblastoma. Branching sinusoidal spaces are surrounded by spindled and giant cells. (H&E)

Differential diagnosis

The distinctive features of giant cell fibroblastoma, particularly the sinusoidal spaces lined by giant cells, together with CD34 positivity, usually allow an accurate diagnosis. Reports of ‘giant cell fibroblastoma’ foci in other lesions, such as giant cell angiofibroma and hemangiopericytoma, indicate that similar changes may rarely be found in other tumors.

DERMATOFIBROSARCOMA PROTUBERANS

DFSP is a slow-growing, locally aggressive tumor of intermediate malignancy, and of disputed histogenesis, with a marked tendency to local recurrence, but that rarely metastasizes.⁸⁸⁷⁻⁸⁹⁰ Its annual incidence in the United States is 4.2 per 1 million;⁸⁹¹ it is slightly less in one area of France.⁸⁹² It occurs in all races.^{893,894} It has a predilection for the trunk and proximal extremities of young and middle-aged adults,⁸⁹⁵⁻⁸⁹⁷ but other sites are rarely involved.^{885,898-901} Congenital and familial cases and onset in childhood are all rare.⁹⁰²⁻⁹¹² Congenital cases may be misdiagnosed as benign lesions because of their deceptive appearance;⁹¹³⁻⁹¹⁵ they may be mistaken for a vascular birthmark.⁹¹⁶ In the United States, DFSP is more common in blacks than in whites, and there is a higher incidence in women than in men.⁸⁹¹ The lesions are solitary or multiple polypoid nodules, often arising in an indurated plaque of tumor.⁹¹⁷⁻⁹²⁰ Approximately 40% of cases are initially nonprotuberant.⁹²¹ Atrophic variants are uncommon; they may be difficult to diagnose clinically.^{902,909,922-925} The involved area of skin measures from 0.5 to 10 cm or more in greatest diameter. A violaceous or red color is sometimes present, but at other times the nodules are flesh colored.⁹¹⁸ A history of previous trauma at the site is sometimes given.^{898,926} Accelerated growth has been reported during pregnancy;⁹²⁷ metastases followed pregnancy in one case.⁹²⁸ Previous arsenic exposure was present in one case.⁹²⁹ It has also been reported in a patient with X-linked agammaglobulinemia,⁹³⁰ in a renal transplant recipient,⁹³¹ at the site of prior leishmanization, in a smallpox vaccination scar,^{932,933} and in a tattoo.⁹³⁴ DFSP has also been reported in association with a nuchal-type fibroma⁹³⁵ and with multiple spindle cell lipomas.⁹³⁶ Rarely, DFSP may masquerade as a skin tag,⁹³⁷ a cyst,⁹³⁸ or as a primary breast lesion when located in the skin of the breast.⁹³⁹

Local recurrence occurs in up to one-third of all cases.^{918,940} Lower recurrence rates have been reported using Mohs micrographic

surgery.^{941,942} Hematogenous metastases, although rare,⁹⁴³ are more common than those to regional lymph nodes.⁹⁴⁴⁻⁹⁴⁷ In a 2007 study, the relative 5-year survival was estimated to be 99.2%.⁸⁹¹ Progression of recurrent DFSP to a malignant fibrous histiocytoma,⁹⁴⁸ and the development of fibrosarcomatous, neurofibrosarcomatous, or myxofibrosarcomatous areas in DFSP, have been well documented, occurring in 10–15% of cases.⁹⁴⁹⁻⁹⁵³ Progression to fibrosarcoma is associated with microsatellite instability and p53 mutations.^{954,955} The fibrosarcomatous variant of DFSP is said to be a much more aggressive lesion with metastatic potential;^{956,957} however, a study of 17 cases showed that only 4 cases recurred and none developed metastasis within the 5-year follow-up period.⁹⁵⁸ The lesions were treated initially with wide local excision with negative margins.⁹⁵⁸ In a study from the Mayo Clinic on the prognostic significance of fibrosarcomatous transformation, four patients (10%) had metastases and two patients died of disease.⁹⁵⁵ Giant cell fibroblastoma has a close relationship with DFSP; either tumor may recur with features of the other (discussed previously).

The **pigmented storiform neurofibroma of Bednar (Bednar tumor)** is now regarded as a pigmented variant of DFSP.⁹⁵⁹⁻⁹⁶⁶ It is an exceedingly rare tumor that accounts for only 1–5% of all cases of DFSP.⁹⁶⁴ It occurs in a similar clinical setting to DFSP but, as yet, no metastases have been recorded. It is thought to represent the colonization of a DFSP by melanocytes.⁹⁶⁷ Dermal melanocytosis has been reported in one case, raising the possibility of neuroectodermal multidirectional differentiation for both this and the DFSP components.⁹⁶⁸ A case has been reported that arose at the site of a previous immunization.⁹⁶⁹ A congenital variant has also been reported.⁹⁷⁰ A fibrosarcoma component has also been reported in this pigmented variant of DFSP.⁹⁷¹

The **myxoid DFSP** is uncommon. In a review of 23 cases from his consultation files, Fletcher found that the majority of cases were found on the extremities and the head and neck. Three cases were from the anogenital region.⁹⁷² Clinical follow-up in 8 cases revealed local recurrence in 2, but there was no evidence of metastasis.⁹⁷²

Although DFSP is traditionally regarded as a fibrohistiocytic tumor, several ultrastructural and immunohistochemical studies have questioned this viewpoint;⁹⁷³ a neuroectodermal origin has also been suggested, but the immunophenotype (see later) does not support this concept. Fletcher and colleagues commented that “the most pragmatic solution at this time may be to regard these tumors as a heterogeneous group, in line with the pluripotentiality of mesenchyme.”⁹⁷⁴ A fibroblastic origin seems most likely on the basis of the immunophenotype and ultrastructure of the cells.⁹⁷⁵ Platelet-derived growth factor has been identified in DFSP and other fibrohistiocytic lesions.⁹⁷⁶

Cytogenetically, DFSP is characterized by a reciprocal translocation, t(17;22)(q22;q13), and a supernumerary ring chromosome derived from the translocation r(17;22).^{901,977} The translocation can be demonstrated by FISH analysis (Fig. 34.37). Other rare abnormalities have been found. Cloning studies reveal that the translocations result in the fusion of two genes, *COL1A1* and *PDGFB*, related respectively to the formation of type I collagen and platelet-derived growth factor.⁹⁷⁷⁻⁹⁸⁰ A recent study has shown that *COL1A1-PDGFB* fusion can be identified in virtually all cases of DFSP when investigated by newly developed multiplex RT-PCR and FISH assays.⁹⁸¹ Cases without a detected cytogenetic abnormality are in the literature from earlier days.⁹⁸² This fusion product has also been demonstrated in the granular cell and myxoid variants, in the Bednar tumor, and in giant cell fibroblastoma.^{871,983,984} A 2008 study suggested that genomic gains of *COL1A1-PDGFB* are associated with the histological evolution of giant cell fibroblastoma into DFSP.⁹⁸⁵

Macroscopically, the cut surface of the tumor nodules appears firm and is gray-white in color. Recurrent lesions with abundant mucin may have a more glistening appearance. The pigmented variant may appear slate gray or black if sufficient melanin is present within the tumor.⁹⁶⁴

Aggressive surgical treatment with margins up to 5 cm has been recommended for this tumor.⁹⁸⁶ The recurrence rate is higher on the

Figure 34.37 FISH of dermatofibrosarcoma protuberans. With FISH analysis, a 'breakapart' probe demonstrates single red (COL1A1) signals in several tumor cells, indicating the presence of the t(17;22) translocation. (FISH image courtesy Mark R. Wick, M.D.)
